This is a digital copy of a book that was preserved for generations on library shelves before it was carefully scanned by Google as part of a project to make the world's books discoverable online.

It has survived long enough for the copyright to expire and the book to enter the public domain. A public domain book is one that was never subject to copyright or whose legal copyright term has expired. Whether a book is in the public domain may vary country to country. Public domain books are our gateways to the past, representing a wealth of history, culture and knowledge that's often difficult to discover.

Marks, notations and other marginalia present in the original volume will appear in this file - a reminder of this book's long journey from the publisher to a library and finally to you.

**Usage guidelines**

Google is proud to partner with libraries to digitize public domain materials and make them widely accessible. Public domain books belong to the public and we are merely their custodians. Nevertheless, this work is expensive, so in order to keep providing this resource, we have taken steps to prevent abuse by commercial parties, including placing technical restrictions on automated querying.

We also ask that you:

+ *Make non-commercial use of the files* We designed Google Book Search for use by individuals, and we request that you use these files for personal, non-commercial purposes.

+ *Refrain from automated querying* Do not send automated queries of any sort to Google's system: If you are conducting research on machine translation, optical character recognition or other areas where access to a large amount of text is helpful, please contact us. We encourage the use of public domain materials for these purposes and may be able to help.

+ *Maintain attribution* The Google "watermark" you see on each file is essential for informing people about this project and helping them find additional materials through Google Book Search. Please do not remove it.

+ *Keep it legal* Whatever your use, remember that you are responsible for ensuring that what you are doing is legal. Do not assume that just because we believe a book is in the public domain for users in the United States, that the work is also in the public domain for users in other countries. Whether a book is still in copyright varies from country to country, and we can't offer guidance on whether any specific use of any specific book is allowed. Please do not assume that a book's appearance in Google Book Search means it can be used in any manner anywhere in the world. Copyright infringement liability can be quite severe.

**About Google Book Search**

Google's mission is to organize the world's information and to make it universally accessible and useful. Google Book Search helps readers discover the world's books while helping authors and publishers reach new audiences. You can search through the full text of this book on the web at `http://books.google.com/`

# INDEX.

Absorbing Power of the Bladder, 443.
About Mushrooms, 750.
Abdominal Hysterectomy, 136.
Abortive Treatment of Gonorrhœa with Oil of Cinnamon, 299.
Abscess of the Tonsil, 183.
Absorption of Salicylic Acid by the Skin, and its use in Acute Rheumatism, 107.
Abscesses and Ulcers of the Cornea, 679.
Acetanilid and Dover's Powder in Grippe, 476.
Acromegaly, 864.
A Case of Extreme Low Temperature, 911.
Acute Retrogressive Muscular Atrophy, 95.
Oedema of the Larynx—Intubation, 331.
Puerperal Cellulitis and True Pelvic Abscess. Charles P. Noble, M. D., 742.
Muscular Atrophy of the Shoulder Following a Traumatic Injury to the Cranium, 684.
Tonsillitis, 369.
Acting Assistant Surgeons, 373.
Action of Permanganate of Potassium in Rendering Morphia Inert, 335.
Aetiology of Headache, 732.
Air Embolism, 769.
Alopecia Areata, 142.
Alkaline Nitrates in Malarial Poisoning, 384.
American Achievements in Surgery, 541.
Medical Association, San Francisco, Cal., 400, 481.
Grippe, or Myxoidœdema, Carl Seiler, M. D., 457.
Surgical Association, 481.
An Epidemic of Typhoid Fever Caused by Milk, 819.
Observation of the Effects of Erysipelas on Epithelial Cancer, James Collins, M. D., 609.
Anatomical Construction of Some of the Granular Swellings of the Integument, 22.
Antipyrin as a Hemostatic and an Antigalactagogue, 369.
An Epicystomy, 716.
Antisepsis of Fissures of the Nipple, 386.
Antipyretic Drugs, 732.
Antiseptic Obstetrics, J. S. Dukate, M. D., 77.
Anæmia of Miners in Children, 74.
Apparatus for Preventing and Correcting Deformities Occurring After Excision of the Knee-Joint, 583.
Apomorphine for Hysteria, 336.
Appendicitis From a Medical Standpoint, T. L. McDermott, M. D., 813.
Appendicitis, 248.
Arsenic and Cancer, 445.
Ascitic Distention of the Abdomen Mistaken for Pregnancy, T. Ridgway Barker, M. D., 852.
Aseptic Surgery for the Country Practitioner, 661.
Asthma, 773.
Atavism Involving Three Generations, 66.
Atropine in Morphinism, 443.
Aural Reflex of Unusual Character Due to Impacted Cerumen, 299.

Base Ingratitude, 615.
Bathing, Swimming and Driving as causes of Aural Diseases, Laurence Turnbull, 810.
Bicarbonate of Soda in Diabetic Coma, 170.
Bill to Establish a Department of Public Health, 581.
Bismuth in Gastric Disease, 733.
Biological Treatment of Enteric Fever, 225.

BOOK REVIEWS.

A Clinical Text-Book on Medical Diagnosis, Oswald Vierordt, 257.
A Practical Treatise on Materia Medica and Therapeutics, Roberts Bartholow, M. A., M. D., L. L. D., 110.
A System of Genito-Urinary Diseases, Syphilology and Dermatology, 798.
A Text Book of the Diseases of Women, Henry J. Garrigues, A. M., M. D., 585.
Surgery—Berne B. Gallendeet, M. D., and Charles N. Dixon-Jones, M.D., 110
The Modern Climatic Treatment of Invalids with Pulmonary Consumption in Southern California, P. C. Remondino, M. D., 257.
The Child Physically and Mentally—Advice of a Mother According to the Teaching and Experience of Hygienic Science. Guide for Mothers and Educators, Bertha Meyer, 110.
The Standard Dictionary, 831.
The Physicians Visiting List for 1894, 111.
The Review of Reviews, 221.
Traite des Retrecissements, Dr. P. Harmonic, etc, 220.
An American Text-Book of the Diseases of Children, Louis Starr, M. D., Assisted by T. S. Westcott, M. D., 831.
Antiseptic Therapeutics, E. Trouessart, 439.
An Outline of the Embryology of the Eye, Ward A. Holden, A. M., M. D., 110.
Clinical Gynecology; Hand-book of Diseases Peculiar to Women, Thomas More Madden, M. D., F. R. C. S., 257.
Essentials of Minor Surgery, Bandaging and Venereal Diseases, Edward Martin, M. D., A. M., 110.
Essentials of Bacteriology, M. V. Bell, M. D., 111.
Etude sur le Dermographisme ou Dermoneurose Toxivasomotricie, Toussant Barthelemy, 220.
Flint (A.) on Treatment of Fermentative Dyspepsia with Subgallate of Bismuth, 221.
Manley on Hernia, 220.
New Truths in Ophthalmology, G. C. Savage, M. D., 110.
On Gout, as Peripheral Neurosis, Willoughby Francis Wade, 220.
Pain in its Neuro-Pathological, Diagnostic, Medico-Legal and Neuro-Therapeutic Relations, J. Leonard Corning, A. M., M. D., 800.

Brannan (J. W.) on Quinsy and its Treatment by Early Incision, 225.
Bremann (Helle) treatment of Gunshot Wounds of Abdomen, 263.
Brief Study of Some Ancient Epidemics and Their Relation to Influenza, Roland G. Curtin, M. D., and Edward W. Watson, M. D., 490.
Bromide of Gold and Arsenic, 769.
Burns, 408.

Calomel as a Diuretic in Nephritis, 542.
As an Antipyretic, 870.
Soap in Syphilis, 642.
Carcinoma and Endothelioma of the Ovary, 21.
Care of Infants and Young Children According to the Bible and Talmud, 30.

Case of Paraldehyde Habit, S. H. Stucky, M. D., 91.
Of Diphtheria, 688.
Of Primary Tuberculosis of the Mastoid Process, 870.
Of Microcephalus, 467.
Of Lithopædian, 464.
Of a Leg Showing Right Angle Flexion and Rotation After Incision of the Knee, 583.
Of Hysterical Alexia, Cured by Suggestion, 863.
Of Epilepsy, 467.
Of Sore Throat from Copaiva, 817.
Of Incarcerated Hernia of a Diverticulum of the Intestine, 53.
Of Multiple Neuritis (Alcoholic) Herman D. Marcus, M. D., 815.
Of Accidental Hernia, 543.
Of Rheumatism Without History of Traumatism or Constitutional Taint, 331.
Of Primary Tuberculosis of Laminæ and Spinous Processes of the Vertebral Column, 290.
Of Simultaneous Extra and Intra-Uterine Pregnancy, 308.
Of Spontaneous Absorption of a Cataractous Lens, T. B. Schneideman, M. D., 530.
Of Erysipelas, P. Guntermann, M. D., 319.
Of Typhoid Fever with Several Relapses, Mary H. Thompson, M. D., 557.
Capillary Bronchitis, 851.
Castor Oil Administered Agreeably, 428.
Catarrhal Otitis, 409.
Catrin on Observations on Mumps, 150.
Causes and Treatment of Migraine, 694.
Cellular Radiation, G. P. Hachenberg, 844.
Certain Sign of Death, 660.
Change of Meeting Place, 364.
Chemistry of Fatigue, 36.
Chloride of Ammonium in Cystitis, 409.
Chlorosis with Menorrhagia, 747.
Chloroforming in Sleep, 770.
Chloroform Narcosis, 476.
Chloralamid a Remedy for Sea Sickness, 119.
Chloroform as a Hæmostatic, 35.
In Labor, 263.
In Chronic Gastric Ulcer, 189.
Cholera and the Unsanitary Condition of Havre, 507.
Chronic Anæmia, 184.
Dyspepsia in Infants, 320.
Gonorrhœa in the Male, 643.
Rheumatic Throat Diseases, 384.
Retro-Bulbar Neuritis, W. Cheatham, M. D., A. B., 90.
Chrysorobin in Psoriasis, 332.
Cigarette Smoking, 374.
Cinchona in Malarial Affections, R. G. Sayle, M. D., 153.
Citric Acid in Diphtheria, 788.
Clinical Contributions to Abdominal Surgery, 801.
Lectures on Pediatrics, A. Jacobi, M. D., 587.
Cocaine in Small-pox, 298.
Wakefulness, 252.
In Otitis Media, 317.
Coffee Versus Digestion, 866.
Cold Hands and Feet, 246.
Compresses in Diseases of the Chest, 855.
Complicated Colles' Fracture, E. J. Kempf, M. D., 313.
Conditions Justifying Removal of the Testicle in Radical Operations for Inguinal Hernia, with a Report of Three Successful Cases, Thomas S. K. Morton, M. D., 603.
Of the Urine in Relation to Anæsthesia, 36.
Congenital Absence of Lung, 698.
Hypertrophy, with Report of a Case of Congenital, Hypertrophy of the Foot, 291.
Absence of Right Kidney and Suprarenal Capsule, 35.
Condensed Milk, 298.
Confusion of Gastric and Intestinal Dyspepsia, 209.
Congratulatory Address, Theophilus Parvin, M. D., 486.
Contributions to Obstetrics and Diseases of Women, Theophilus Parvin, M. D., 839.
Contagiousness of Tuberculosis. J. C. Sprae, M. D., 842.
Contribution to the Theory of Epidemic Night Blindness, 135.
Contributory Negligence of Patient as Defense to Charge of Malpractice, 141.
Conservative Cæsarean Section; Three Years Later Porro on the Same Patient, 168.
Considerations on the Subject of Chorea, J. A. Baughman, M. S., M. D., 229.
Convallaria Majalis in Heart Affections, 319.
Convulsions in Young Children, 693.
Cotton-Root as a Hemostatic in Menorrhagia, 612.
Cough, 733.
Coryza, 170.
Cornutine During the Puerperium, 318.
Creasote in Chronic Pyelo Nephritis, 173.
and Sulfonal in Whooping Cough, 384.
Croupous Pneumonia in Children, 76.
Cured Fracture Involving the Atlas and Axis, 756.
Cyst or "Hydrocele" of Nuck's Canal, 189.
Cystic Tumor of the Orbit, 721.
Ovary, 143.
Cystitis, 769.

Dangers of Piercing the Ears, 445.
Of Infection of Personal Contact, 252.
From External use of Salicylic Acid, 20.
Of Cocaine in Salves, 386.
Dawbarn (R. H. M.) on Treatment of Sprains, 189.
Death from a very Small Calculus in the Bladder, 916.
Of Dr. John H. Rauch, 540.
Delayed Union In Fracture, Thos. G. Morton, M. D., 787.
Demonstration of a New Surgical Engine, 756.
Dentition with Diseases of the Teeth, as a Cause of Ear Disease, Laurence Turnbull, M. D., 451.
Diabetes Mellitus, 914.
Diabetes Mellitus, with Report of two Cases, Geo. F. Bates, A. M., M. D., 483.
Diagnosis of Diphtheria, 869.
Diarrhœa of Dentition, 170.
Dietary in Typhoid Fever, 616.
Digitalis in Frost-Bites, 169.
Dilatation of Cervix for Dysmenorrhœa, 298.
Diphtheria, 361, 226.
Conveyed by a Fog, 297.
Disputed Points in Pelvic Pathology and Surgery, Joseph Price, A. M., M. D., 343.
Displacement of Semi-lunar Cartilage by Injury; Replacement by pressure, 145.
Double Hydrosalpinx and Cystic Ovaries, 253.
Drainage of Pyosalpinx through the Uterus, 179.
Dry Scaly Conditions of the Epidermis, 517.
Dysentary and Diarrhœa, 320.
Dysmenorrhœa—Its Causes, Symptoms, and Early Treatment, M. F. DeHart, M. D., 10.
Dysmenorrhœa, 924.
Dyspeptic Vomiting in Children, 319.

Early Symptoms of Rheumatoid Arthritis, 75.
Easy Method of Keeping Warm, 478.
Ectopic Gestation, 288.
Echinococcus Cysts, 817.

EDITORIALS.

A Cordial Invitation, 749.
A National Department of Public Health, 572.
A Study of Hypnotism, 613.
A Wise Proposal, 171.
Increase of Insanity in the United States, 57.
Influenza, 211.
International Sanitary Conference, 394.
Medical Experts and the Value of their Testimony, 469.

"No Matter:" "Never Mind," 539.
Prospective, 28.

### TREATMENT OF OLD CASES OF HIP DISEASE.

WM. E. WIRT, A. M., M. D., PH. D.,* Cleveland, Ohio.

On the streets of any of our larger cities one will see many examples of cripples walking with one limb either dangling in the air worse than useless, due to the extreme flexion at the hip with abduction, or else they will be seen walking very imperfectly on a high built-up shoe. It is the treatment of these cases and also that of convalescent hip disease to which I wish to call your attention.

There is no doubt that if convalescent cases of hip disease were carefully and persistently treated during the long period to complete recovery, whatever deformity had existed up to this time, and that which accompanies this period, could be entirely overcome without operation. During the convalescent period, the spasm of muscles having entirely disappeared, traction is not considered necessary—a brace that simply gives protection to the joint in walking is sufficient. This protection from jar in walking is especially required in the first part of the step, *i. e.*, at the time when the heel is brought to the ground.

This can be easily accomplished by using the caliper, the upper part of which is similar to the ordinary hip brace with stem, pelvic band and perineals, the lower part cylindrical in shape, turned at right angles to the stem and passing through a hollow cylinder in the heel. The stem and perineals should be of such length that the heel of patient, though inside the shoe, should bear no weight, all weight being taken up by perineals.

The brace may be jointed at the knee, and the patient can then get about quite easily and with comfort. In small children the joint is unnecessary, and in clinical patients the question of additional expense debars the joint. Dr. A. B. Judson, of New York, devised a brace for these cases, using one perineal band—he calls it the perineal crutch.

When shall a case of hip disease be considered to have progressed far enough to permit the removal of the extension splint and the substitution of a convalescent brace? The solution of this problem is much a matter of judgment. It is better to allow the extension splint to be worn unnecessarily long than for the substitution to be made too soon. It is essential that one wait until all pain and acute symptoms have been absent for some months, and there exists no muscular spasm. Likewise during the convalescent stage it is better that the protective splint be worn longer than necessary than for too short a period. From one to three years will usually be necessary. The discontinuance of the protective splint should

*Prof. of Orthopedic Surgery in Medical Department of Wooster, Cleveland, Ohio; Orthopedic Surgeon to Cleveland Hospital for Women and Children; Member of the American Academy of Medicine; Member of the American Orthopedic Association; Chairman of Committee on Defective Classes of Ohio State Association of Charities and Correction, etc.

be a gradual process, the splint only being removed part of the day or for short walks; but when the patient intends to do considerable walking the splint should be resumed. After some days' or weeks' trial of leaving off the protective splint, should it be found that the joint is becoming painful and sensitive, it is better to return to the constant wearing of the splint for six months or a year longer.

OLD HIP CASES WITH DEFORMITY.

The deformities requiring correction are flexion and adduction. These deformities produce an apparent shortening of the limb, or, as it is called, "practical shortening," in contradistinction to real shortening, which latter may be quite small while the former is considerable. Abduction exists as a deformity, but, as it increases the practical length of a limb already actually shortened by disease, the deformity is rather of an advantage than otherwise and does not ordinarily require correcting, unless excessive. In adduction, besides shortening, there is tilting of the pelvis. In order to bring the foot down in the act of walking in those cases where there is fixation at a moderate angle of flexion, motion must take place at the spine, thus producing lordosis; and where the angle of deformity is great, it may be nearly or quite impossible to get the foot down. In these cases a practical lengthening of the leg is obtained by building up the shoe. When the deformity is of such a grade as to seriously interfere with progression, surgery is called upon for relief from the condition.

I have been surprised in several instances of old cases of hip disease with considerable deformity where it appeared that the ankylosis was very firm and bony, that on the application of continuous extension in bed for a few weeks the deformity would be considerably reduced. This had led me to believe that many if not most of these cases should be given a trial of extension in bed for reduction of deformity before proceeding to operative measures, or at least before performing an osteotomy. By the use of adhesive straps to the leg, with weight and pulley, extension can be obtained, and counter-extension secured by the foot of the bed being raised or by the use of the perineals with attachment to head of bed. With considerable adduction it is a good plan to make counter extension by a perineal to the other hip. After a trial of extension in bed with a failure to reduce deformity, there remains as means of correction: 1. Brisement forcé, with or without myotomy, tenotomy, faciotomy, etc. 2. Osteoclasis. 3. Osteotomy.

Brisement forcé should be limited in use to those cases in which there is evidently only fibrous ankylosis. There is the danger in the use of too much force of fracturing the thigh bone at an unfavorable point; and again there is the danger of relighting the tubercular process. If there is considerable shortening of the flexor or adductor muscles, or of the fascia, subcutaneous division of these structures will greatly aid in rectifying the position of the limb. Frequently the capsule of the joint is found shortened, and, in some cases, an open incision down to the joint (cutting everything which obstructs, including the capsule) is found to be necessary before the limb can be straightened. After the limb is straightened it should be encased in a plaster-of-Paris spica, or fixed by means of extension. Absolute rest is necessary for a variable period; and should there be heat about the joint, giving evidence of some inflammation being produced, bags of ice placed about the hip frequently reduces this activity in a short space of time. After all danger of inflammatory action is past the patient should be fitted with a protection splint and allowed to get about.

Osteoclasis and osteotomy are reserved for those cases in which there exists bony union or a fibrous ankylosis of a very firm character. It is true that osteoclasis is sometimes the result of brisement forcé, but this is accidental and not the desire of the operator. In performing osteoclasis appliances are used to hold the pelvis rigid while force is exerted on the limb sufficient to fracture the bone or break up the ankylosis; but the point of fracture is so uncertain and the operation as a whole lacks precision and is so unscientific that it has been replaced by osteotomy. Osteotomy is by far the most satisfactory operation for the rectification of deformity in a bony ankylosed hip. This operation has been performed at different points near the head of the bone. Adams' operation was a division of the bone at the neck. Sayre and Barwell divided the bone between the greater and lesser trochanters, while Gant

performed osteotomy just below the trochanter minor.

This latter operation, now admitted the best by most surgeons, is based on the anatomical reasoning that the resistance of the psoas and iliacus being set free, a return of the deformity is not to be expected; also that by operating at a lower point than had formerly been done, the operator is more likely to strike healthy bone and less likely to relight the old inflammation.

GANT'S OPERATION.

Having determined that all inflammatory action in the joint has ceased and that probably nothing short of an osteotomy will correct the deformity, the night before the operation the thigh is encased in a dressing of soft soap, or soap liniment, with proper outside bandages. By the next morning it will be found that the outer layers of epidermis are softened and will readily wash off. Then ether and alcohol may be used to remove any oily or soapy substances remaining. The patient, under an anæsthetic, is placed on his side with a sand bag between the thighs. The trochanter minor having been marked out, the osteotome is introduced at a point just below the level of this trochanter, on the outer aspect of the thigh. The best osteotome for this work is an instrument whose length should be about seven inches, width of cutting-edge three-eighths to one-half inch. It should be tempered to a hardness between that of a cold-chisel and the carpenter's chisel. The handle should be marked every half inch, to show the depth to which the instrument has penetrated. This is more than theoretically indicated, for I have seen the osteotome driven through the thigh and one and one-half inches into the sand bag. In introducing the instrument into the thigh, the edge of the blade is held parallel to the axis and is made to penetrate the skin, fascia, muscles, periosteum, down to the bone; the blade is then turned at right angles to the limb, and, with sharp blows of a mallet, preferably a wooden one, the osteotome is driven through the bone, being loosed and driven at different angles after every two or three blows. When only a shell of bone remains, the instrument is withdrawn and the fracture completed by manual force. The limb is then brought down to as nearly the horizontal plane as possible, at the same time putting it in a position of abduction. This abduction is to increase the practical length of the limb and is thereby a positive advantage. There is little or no bleeding. The wound in the skin is very small and is covered over by oiled silk or rubber gauze; over this is the antiseptic dressing, and over all is applied a plaster-of-Paris spica reaching from the axilla to the ankle, and it may also include the foot with advantage. The limb is left in the plaster spica from four to six weeks, after which it is removed, the parts examined and measure is taken for a convalescent walking-splint. By the time it is made and applied the limb is strong enough to be used with the aid of the splint. The convalescent splint is worn for three to eight months, or longer.

As a result of these operations we have a practical lengthening of the limb from one to four inches, the limb placed in nearly a line with the body, and in walking the spine is held upright instead of being lordosed, as is required with a flexed limb.

Some time ago I reported in detail the results in sixteen cases following Gant's operation. I give a summary of that report in the table here appended.

(See table on page 4).

From this table we see that the average age of the patient was eleven years, the oldest being sixteen, the youngest five and one-half. We find that the hips were held fixed at an average of 135°, *i. e.*, half way between a straight leg and one held at a right angle. By the operation they were brought down on an average of 36°, thus bringing the leg to within 9° of being perfectly straight (171°). The average shows a practical shortening of two and a half inches before the operation and only one inch shortening after the operation. There was no motion at the hip in any case before operation, while after operation there was motion at the joint in several cases. All of the cases were improved in their ability to walk—some greatly, others only moderately. There were no untoward symptoms in a single case. We therefore conclude that the operation is a great boon to those having considerable deformity as the result of hip disease.

| Case. | Age. | Time Spica Remained On. | Angle of Fixation Before Operation. | Amount Leg was Brought Down. | Greatest Extension After Operation. | Adduction before Operation. | Practical Shortening Before Operation. | Increase in Practical Length. | Practical Shortening After Operation. | Am't of Motion at Hip before Operation. | Amount of Motion at Hip After Operation. | Ability to Walk After Operation. |

# COMMUNICATIONS.

## WHAT THE MORTALITY SHOULD BE IN MATERNITY HOSPITALS OR PRIVATE OBSTETRIC PRACTICE.

JOSEPH PRICE, A.M., M. D., PHILADELPHIA.

There is very much skepticism as to the statistics of mortality in maternities and private practice. About one fact there can be no dispute, that is, that there are too many deaths from infection and septic causes. The mortality from these causes both in maternities and in private practice, should be nil. In hospital and private practice there will be occasional unavoidable deaths from chronic kidney disease, consumption, cancer or other incurable disease. The common causes of mortality are avoidable and are wholly absent in the Preston Retreat and other of our maternities. Labor is a perfect natural process when all the conditions are normal and an ideal cleanliness is rigidly observed. Where the conditions are abnormal or there occurs those accidents to parturition prompt and skillful surgery will save life in nearly all cases. Our obstetrics have been aided by our greatly advanced knowledge of the structures of parts, our increased knowledge of puerperal conditions, both normal and pathological. The fevers of the lying-in period have been banished from the lying-in Hospital—formerly rarely free from these and frequent in private practice. The intelligent and conscientious physicians by a more careful watching of cases have made the accidents of maternity less frequent and fewer mothers are hurried to premature death.

Deaths in child-birth are noted more than formerly and the causes inquired into. Happily the mother begins to count for somebody and the causes for her needless sufferings are reckoned. There are no cases more dependent upon the care and ability of others than that of the mother and her new-born infant. There is no responsibility more vital than that of those attendant upon them. They should have skill and knowledge of their duty in all its manifold relations. The responsibility in such cases is too often treated lightly. It would be startling to know, with all our boasted advances, how many mothers and infants are sacrificed to ignorance. The awkward, slovenly and unskillful obstetrician, bad hygienic invironments and ignoront nursing—these have the most to do with the mortality in these cases. It is the skilled experience of the physician, careful, intelligent, and trained nursing, the cleanliness and better sanitary conditions that give to maternities their advantage. Make external conditions healthy, and there will be few or no deaths in maternity cases from septic causes. The advantages of the Preston Retreat, the Sloan, and maternites of modern build, lies in their construction with scrupulous regard to the best hygienic arrangement, in the use of appliances which have stood the severest tests of sanitary science, where the patients are isolated, far removed from the channels of septic infection. With the advance of general intelligence there is a better recognition of the vital importance of the best hygienic conditions, and stronger and louder grows the demand that, in the service of these institutions, to the bedside of mothers shall be called only those of skill, and the knowledge which comes of long and patient study and wide experience. The fact is coming out into strong light that two lives are involved. Men pass out of our colleges to active maternity work without ever having attended a maternity case. The time is not distant in the future when the directors of maternity hospitals will not dare to appoint a man to *direct* or have *official charge* of such *vital interests* without a rich, practical experience and sound judgment. They will be held responsible for the success of their trust, and it is to be hoped will be held *criminally* responsible for the choice of a person to such trust with no more pride of personal cleanliness and cleanliness of environments than a stable boy, dirty in all the term implies—morally and personally. The physician who stands at the bedside of the mother should have knowledge of

his work in all its details, should be ready, quick and full of resource, and have morals upon which the most penetrating search light can be turned.

The Preston Retreat had thirteen hundred and thirteen consecutive cases without a death from any cause. Fourteen hundred cases with one death from mania. The Board of Directors and friends of the institution may well feel proud of this Record when it is contrasted with the good records of the best maternities of Europe. At the Imperial Lying-in Hospital at Vienna the death rate from 1881-7 was 7 per 1,000. At the Paris maternity, from 1882-7 the average had been 11 per 1,000. At one of the chief materanties in England 6 in 1,000 and through out England and Wales was 1 in 200.

But the mortality in child-birth does not represent all the mischief. By ignorance and want of skill many women are rendered sufferers for life, useless to their families, friends and society. There are advantages in favor of the mothers in rural sections over those of the dense populations of the cities—they have plenty of fresh air, healthy and moderate food and with them there is less *ignorant and vulgar tight rope lacing.*

The Retreat has never refused admission to married women. In its practice it has kept strictly within the restrictions of the endowment through the charity of which it was founded and by which it is maintained. There has never been any attempt at that species of legerdemain which characterizes the management of some institutions to divert the charity of the institutions into other channels than those intended by the founder. The affairs of the institution in all their details receive the attention of the Directors who are cultured, honorable men from the body of the community, representative of varied business interests and many of them actively identified with other important charities.

Hundreds of unmarried women have applied for admission, who under the requirements of the endowment had to be refused and referred to other institutions. Both from professional and humanitarian motives. I should have been glad to have admitted these greatly-wronged and unfortunate women, but neither the directors nor I had any election in the matter. From a health-standpoint these unmarried women were greatly preferable, as patients, to very many of the married ones admitted. Many of the married ones coming within the charity were poor, wretched, badly-fed and meagrely clothed. Many of them coming out of dense communities, narrow impoverished environments, a poisoned atmosphere, had been neglected and beaten by drunken and beastly husbands, so that they possessed but little stamina, mental, moral or physical with which to encounter the perils and endure the sufferings of maternity.

The Preston Retreat is the only maternity where patients are cared for the same length of time, six weeks, thus adding four weeks to the time of other maternities, and further adding to the time within which death might occur from puerperal or other causes, and thus increasing the statistics of the mortality of the institution. We feel that we are not claiming too much, when we say that the Retreat under the policy of its Directorship has exerted a wide, extending and greatly beneficial educational influence. It has been visited by physicians of every civilized foreign country, and by many eminent representative physicians of every state of the American Union. The object and motive of these physicians was to study the plan of building, sanitary arrangements, and methods of management, and the verdict of all has been gratifying. There is yet another educational feature associated with its managemen one that cannot be otherwise than far reaching in happy results, that is the thoroughness with which nurses are trained for their responsible duties. The trained nurse is fast becoming as important a personage in the lying-in chamber as the physician. The demand is for cleanliness, intelligence, the very best and most thorough training in all the many qualities essential to the successful nurse.

Paint the whole of this liquid each evening on the affected side. The temperature quickly falls, an abundant perspiration takes place, and the effusion becomes soon absorbed.—*Med. Press and Circular.*

## SYMPOSIUM ON EXTRA-UTERINE PREGNANCY.

TRANSLATED BY M. B. WERNER, M. D., PHILADELPHIA.

SUTUGIN gives his views on the subject of abdominal pregnancy, which correspond largely with those of Mactecki, R. Teuffel, Bandl, and reporting 2 cases which came under his own observation. Patient aged 33; second pregnancy; 4th month, fell from a street car; general peritonitis; patient was 2½ months in bed. The following January, 1890, a cystic tumor of irregular form could be felt in the abdomen, reaching three fingers above the umbilicus. The small parts of the living fetus could be readily felt. In order to relieve the patient, Sutugin made an opening in Douglass' cul-de-sac, which was followed by a large quantity of blood; the opening was tamponed with iodoformized marly. The heart's action being weak, it became necessary to desist from further operation; the patient died two hours after.

*Autopsy.*—Behind and somewhat above the enlarged uterus was found the sac containing the fetus. The placenta was found attached to the posterior wall of the uterus, the right broad ligament and the deepest portion of the Douglass' cul-de-sac extending 9 cm. along the rectum. Attached to the fundus of the uterus was found a pediculated fibro-myoma. The anatomical diagnosis was as follows: *Nephritis Parenchymatosa, Hemorrhagic Acuta, Hydro-Nephrosis, Cystitis Catarrhalis, Endometritis, Graviditas Extra Uterine Abdominalis.* Sutugin sums up in the following manner: Retro-uterine abdominal pregnancy is usually interrupted early by the formation of hematocele; in very rare cases the gestation may go on to term. The early stages of abdominal pregnancies always have their beginning in the uterus. The symptoms of compression of the intestines and uterus appear earlier than in the other forms of ectopic gestation. Aside from the usual uncertain symptoms of pregnancy, examination will disclose a compressible swelling located behind the uterus, that organ itself being enlarged and displaced anteriorly. In the second half of pregnancy there will be found a round, irregular cystic tumor in the abdomen, in which may be felt the small parts of a fetus. Of importance diagnostically is the diminution of the vaginal canal, produced by the mass felt posteriorily giving to the examining finger a sensation of placental tissue. The cervix is usually high and sometimes out of reach. Therapeutically, Sutugin concludes, that when rupture of the sac takes place with hemorrhage, an early opening in the posterior vault of the vagina, laparotomy with complete removal of placenta is indicated.

2. MANDELSTAM reports the following case. Patient aged 24; had previously given birth to one child; not pregnant for 4 years; had been treated during that time for uterine disease. Last menstrual period occurred in the latter part of March, 1891. First of May, collapse, expulsion of the decidual membrane. A tumor could be felt to the right of the uterus. This increased up to the middle of July, to the size of about two fists and was adherent December 31st. There was found a round tumor in the middle of the abdomen, extending 2 fingers above the umbilicus. This was strongly attached to the uterus. In the early part of that month, motion had been felt by the patient. Early part of February there was considerable pain, accompanied by fever 39.5° C.; laparotomy performed February 9th; removal of the dead fetus with its ovisac; it was 39 cm. in length. The free portion of the tumor, after being thoroughly ligated, was removed; recovery complicated by pneumonia. Mandelstem further reports the histories of 11 cases, which have come under his notice during the last eight years. He advises the expectative method of treatment, even if rupture has taken place. Quoting his own words, he states, "that in the majority of cases with absolute rest, strict diet, the use of ice and opium in large doses, hemorrhage can be controlled."—ED(?).

3. MAUERHOFER reports the histories of 4 cases operated upon for ectopic gestation, observed by him in the Frauenklinik, at Berlin since 1878. He advises operative procedures in the first half of pregnancy, performed under aseptic precautions with the aid, if necessary, of tamponing the pelvic cavity. He regards this treatment as the safest even in the most unfavorable cases. Injections of

morphine in the ovisac or the application of electricity is neither used nor advised.

In the second half of pregnancy, if the fetus is living, the latter should receive some consideration so long as it does not interfere with the actual health of the mother. The time for abdominal section being left to the judgment of the physician. If the fetus is dead it is necessary to await the obliteration of the placental circulation, provided sepsis or internal hemorrhage does not make it imperative to perform an entire section.

The tamponade of the small pelvis is considered by him a great advance, since many cases in which it becomes impossible to remove all the placental attachment, one has the seat of such regions at their command for constant attention.

4. MURET describes three cases of tubal pregnancy in the early months, observed by him at the Strassberger Frauenklinik.

CASE I. Tubal pregnancy of the right side, rupture at the end of the first month, hemotocele, carcinoma of the portio-vaginalis. Total extirpation of the uterus, with its adnexa and the hematocele on right side.

CASE II. Tubal pregnancy of left side, rupture of the tube in the sixth week, hematocele, salpingectomy and enucleation of the hematocele.

CASE III. Tubal pregnancy of right side, rupture at the end of second month; tubal mole, hematocele and salpingectomy.

Muret concludes his remarks as follows:

It is important to decide between the complete or partial rupture and expulsion from the tube. A partial escape of the product of conception may result in the tubal mole; the complete escape usually results in the formation of hematocele, which usually ends in the various known complications. In cases of complete tubal abortion, the symptoms of acute internal hemorrhage are less than in the cases of ruptured tube, although some cases have been known to show symptoms of profound shock.

In cases of incomplete protracted abortion, the hemorrhage and destruction of the ovum, frequently leads to the formation of a mole. The hemorrhage, which has taken place into the tube will find its way through the open end of its fimbriated extremity, and thus lead to the formation of a hematocele. As long as the degenerated ovum, or a portion of it, remains in the tube, it predisposes to occasional hemorrhages, in precisely the same manner as in a protracted uterine abortion.

The tubal walls are frequently found quite thin at the place of attachment of the mole and the degenerated ovum, even though the ostium abdominalis is patulous. This thinning is explained by a local distension of the wall in consequence of the hemorrhage. These cases have but one method of treatment, which solves itself down to the removal of the tube. This can only be done through the abdomen, and should never be attempted through the vagina.

5. GRÆFE. Multipara, 37 years. Diagnosis first made was of a pregnant retroflexed uterus of two months, with beginning abortion accompanied by pelvic peritonitis. Later a cystic tumor was found in Douglass' pouch, not connected with the cervix; there was discharge of decidual shreds. This led to a change in the diagnosis to extra-uterine pregnancy of two months. There was sudden collapse of the patient without previous warning. A large retro-uterine hematocle could be felt, no doubt originating from the hemorrhage produced by the rupture of the tube. On the following day, laparotomy, ligation and removal of the tube. Owing to a continuous bleeding in Douglass' pouch, a tampon of iodoform gauze was placed, the end of which was allowed to pass out through the abdominal wall. Drainage soon ceased, and there resulted a collection of pus in the space posterior to the uterus, which evacuated itself through the lower angle of the abdominal wound. A longer drain was inserted, and later, drainage was made through the vagina. The patient made a good recovery.

Graefe concludes that the formation of hematocele following a rupture from an extra-uterine pregnancy, during the early months of gestation, will in no wise insure against the possibility of another hemorrhage into the abdominal cavity, and though even this should not be the case, it usually takes a long time for the absorption of a hematocele, the patient being a sufferer throughout this period, not alone from the presence of the hematocele, but from the pre-existing diseased appendages.

Bearing all this in mind a radical operative interference seems not only the most justiable, but also the most promising to the patient.

6. DOBBERT reports various anatomical investigations. He has studied numerous specimens and concludes that in cases where an abdominal section becomes necessary, the method of Dombrowski is the best. Dombrowski reports 5 cases in the year 1892, treated in this manner for retro-uterine hematocele; 3 out of 5 were directly traceable to tubal disease. Dombrowski's method is as follows: An incision is made into Douglass' pouch through the vagina, which is extended up to the sac of the hematocele; the vagina is tamponed with iodoform gauze. The patient is then placed in the Trendelenberg position, an incision made in the abdominal wall through the linea alba. If the tumor is not adherent to the parietal peritoneum, it is drawn up and the sac attached to the abdominal opening by means of sutures. The contents are then removed, and the sac cleansed; the vaginal tampon is now removed; by means of forceps, a long drain of a gauze is passed through the abdominal wound down to Douglass' pouch and out through the vagina. An additional tampon is placed in the floor of the cul-de-sac. Closure of the abdominal wound down to the tampons. Tampons are removed as often as necessary, their length being guided by the size of the opening; the vaginal drainage lasts the longest.

7. HERZFELD reports eight tubal pregnancies occurring during three months at Schauta's clinic. All cases were operated on by abdominal section with but one death, due to suppurative peritonitis. The etiology of extra-uterine pregnancy was traced in all cases to chronic and inflammatory changes of the uterus and its appendages, primarily due to gonorrhœa or previous puerperal inflammation. Four were traced directly to gonorrhœa, and two to previous pelvic inflammation following labor. Among the eight, two were primapara, one was infected by gonorrhæa, the other complicated by large fibroma. In the six remaining cases the interim between the last conception and the present was respectively fourteen, eleven, ten, nine, seven and five years. This was of especial interest, since the possibility of conception was present in each case. In two cases the period of pregnancy was completed; in one the operation was performed eleven months after supposed conception; in the remaining cases the period of pregnancy ranged between six and eleven weeks. It is of importance regarding diagnosis to bear in mind the difference in the growth of the uterus between ectopic and normal gestation—the uterus developing more in length than width in the ectopic variety. The question, however, becomes more difficult between the extra-uterine and the pregnancy in the uterus unicornus. The author, however, calls attention to the position of the ligamentum uteriteres, as an aid in differential diagnosis.

HERZFELD closes his remarks by giving a careful description of Schauta's method of operation done under strictly aseptic conditions. While it is always desirable to remove the entire ovisac, it often becomes a dangerous proceeding. In the latter case he usually desists in performing a radical operation, uniting the sac to the lower angle of the wound, and drains. Two such cases are reported, in both the fetus was dead.

8. ZEDEL has presented four specimens of tubal pregnancy, having made a careful histological and microscopical study of each. The ovum was imbedded in the tube. The epithelium in the ovisac was flattened, due, in all probability, to pressure. Generally, there is no complete decidual change in the tubal mucous membrane, only a portion being found near the insertion of the ovum. A complete development of the decidua vera being rarely met with. The upper layer of the serotina can be traced to the lower layer of the ciliated epithelium. The decidua tubaria originates principally from the perivascular connective tissue found in the mucous membrane. The author has been able to demonstrate the connection between the arteries and veins and the intervillus space in a tubal pregnancy of fifth week. The loss of the connective tissue and muscular layers and the incident changes following the cell proliferation of the intima, materially favor the increase of blood supply. This latter is, to his mind, the cause of breaking down the serotina and establishing the communication between the lumen of the blood vessels and the placenta.

The author arrives at the following conclusion: that in the beginning of the

fifth week, the intervillus circulation establishes itself, and fetal life is nourished by the maternal blood. The other points in the circulation are the same in tubal as in intra-uterine pregnancy. A decidua reflexa forms in the tube, and is for the development of the ovum until the intervillus circulation has been thoroughly established. Fibrous layer originates not only from the upper layers of the decidua materna, but also from the neighboring structures, the cellular layer of Langhans. The placenta consists of the original villous chorion, and the superficial layer of the decidua. The development of the ovum proceeds in the same manner as in the uterus.—*Schmidt's Jahrb*, No. 9, 1893.

## DYSMENORRHŒA—ITS CAUSES, SYMPTOMS AND EARLY TREATMENT.

M. F. DeHART, M. D. Jersey City, N. J.

In these days when preventive medicine is the favorite theme of all the most scientific physicians, when such thorough investigations are being made into the causes of disease, and all agree that it is so much easier and better to avoid sickness than to effect the most brilliant cures, it seems strange that so little is said on this subject, which is the cause of so much suffering and the first symptom of so many serious life-long diseases which require at last, the entire removal of the uterus, tubes and ovaries to allay pain and restore peace, which unfortunately, even then the patient does not always find until she folds her hands in death.

One reason for this undoubtedly is that women bear this oft-recurring pain without complaint for many years, as they have been taught to look on this as one of the misfortunes of their sex and inevitable. Their mothers, often having had the same trouble, do not look on it as anything alarming, and so content themselves with giving hot drinks, ginger tea or gin, until the pain has worn itself out for that time, but only to return with increasing intensity at the next menstrual period. This from being an occasional occurrence soon becomes a fixed habit, and is looked forward to with dread from month to month.

As it has been so gradual in its progress, no one realizes how strong a hold it has taken, or how much it has undermined the general health, causing nervousness, dyspepsia, and a long train of mental symptoms, which are as much a part of the disease as the pain. Women hesitate for a long time before consulting a physician, fearing that an examination will be necessary or an operation suggested. Some complain that physicians are indifferent to these early symptoms, and make light of this pain, assuring them that it is nothing serious; that all women are the same, and that they ought to marry, which will, no doubt, cure them; or content themselves and pacify the patient with a prescription of morphine, to be used when required; that others, going to the other extreme, advise an operation for every case without trying the effect of medicines or suggesting hygienic measures, which might in the early stages be sufficient for a cure.

In this way the years run on until this once slight functional disturbance has drawn everything into the tangle, and every organ sympathizes, adding its quota to the general misery, so that it is difficult to tell what is cause and what effect, or to know where to begin to unravel the snarl and restore harmony to the disturbed economy.

Listening to the long array of symptoms, and noticing this gradual advance and steadily increasing intensity from month to month, and from year to year, one is forced to ask, "Why did you not come long ago," and "Was there no one with common sense enough to tell you that menstrual pain was *never* natural, but on the contrary, like all other, always a signal of distress," "To notify you that something was wrong, that it was not enough to stupify one's self with anodynes before learning the truth it was sent to announce, and that enduring it with patience was no virtue until an energetic effort had been made to find out the cause and remove it, after which there would doubtless be ample

opportunity to develop this admirable Christian grace."

Among the causes which bring about this unfortunate condition we shall find everything that tends to lower the general health,—indoor life with too little light, air and sun, too little general exercise, and too much persistent use of a few muscles, as in dancing, sewing on a machine, or long standing in stores—too little legitimate occupation for the mind and too much stimulation and excitement of any unhealthy kind causing loss of sleep—imprudent exposure to cold at any time and especially during the menses–irregularities and improprieties of diet causing constipation and general disturbances—senseless and absurd clothing, which is too heavy and too tight about the waist and not evenly covering the body, leaving many parts too much exposed and others overburdened—long unyielding corsets which interfere with free natural movements of the body, pressing the abdominal organs downward and holding the uterus in a cramped and uncomfortable position.

At first the pain is only for an hour or two, either before the menses appear or just after, but if unrelieved, it becomes more severe and lasts longer each month until the premonitory pains occupy the whole week previous to menstruation and the following week is required to recover from its effects, thus three weeks out of the month are given up to this function which should be painless, and no more disturbing than digestion or respiration. This condition prevents exercise, interferes with all work, study and amusements, leaving its victim a chronic invalid shattered in mind and body, of no use to herself and a burden to others. Is it any wonder that she is a prey to whims and fancies—that she aggravates her real sufferings by many that are purely imaginary, thus wearing out the patience of friends and wasting her own life?

It seems scarcely reasonable to suppose that all this trouble can be cured by any one operation however radical, for her whole nature is involved, and she is a wreck physically, mentally and sometimes morally—her will-power is destroyed, and there seems to be no place to begin the work of cure, for medical science is, as yet, often powerless to avert the penalty attached to violated natural laws.

In view of these facts, and I think that any one who has had much experienec with these cases will admit that they are not overdrawn, is it not the part of wisdom to instruct women on this all-important subject, not waiting until irremediable evils have rendered advice and treatment well-nigh useless? Would not a wise preventive treatment be followed by as good results here as in typhoid fever or septicæmia, and can physicians feel that they have done their duty to the families under their care if they have not endeavored to educate them on this subject as well as on other truths of hygiene?

In the early days, a thorough change of habits with careful regulations of the bowels, and Assafœtida gr. iv, three times a day for three days before the expected period, and Assafœtida gr. viij, xii, three or four times during the first day, will often give speedy relief, and if continued for several months will many times effect a permanent cure.

This simple prescription for so formidable an array of symptoms, may seem to many as absurdly inadequate as the old-time advice given to the leper by the prophet to wash in the river Jordan—but simplicity is said to be the height of art, and success is a sufficient answer to all objections.

---

### A Prolonged Fast.

There is reported from Russia a case of unusually long fasting. A young girl of seventeen was overtaken by night near the village of Ruzino in Moscow on the 24th of last November. She took refuge under a small outbuilding covered with straw. During the night it snowed violently, and in the morning the girl was unable to force her way from under the snow. The first day she ate five bits of bread she had with her, after which she had no food but the snow. Fifty-one days later she was discovered buried under three feet and a half of snow. On being taken to the hospital on January 14th, she was in a state of extreme exhaustion and unable to move a limb, though entirely conscious. There was a general cutaneous anasarca. The mucous membranes were excessively pale, and there was no trace of panniculus adiposus. The muscles were much atrophied. The respiration was 26; the pulse 84, small and feeble; the temperature 38° C. For the next two days she remained semi-conscious and somnolent, but rapidly recovered, and at the end of a week was able to take hospital diet.—*Ex.*

# SOME POINTS OF INTEREST TO THE MEDICAL PROFESSION.*

SENECA D. POWELL, M. D., New York.

In accepting the Presidency of the Medical Society of the County of New York, with the duty and responsibility of presiding over the deliberations of a body so justly renowned and influential, I cannot but be sensible of the honor bestowed and the confidence expressed by your selection. You have my thanks; and I hope that I may be able so carefully and impartially to discharge the duties of the office that your confidence will be justified.

I yield to no one in appreciation of the dignity of this organization, and the importance of its influence. It is the ancient and legally recognized authority upon professional standing and medical ethics. The size and character of its membership, with its location in this cosmopolitan city, make it a power in our profession, perhaps, unequalled by any like association in this country. Its spirit is contagious. Its deliverances are esteemed as professional oracles. Its efforts towards any object carry the prestige, power and effectiveness, which naturally pertain to a body of men distinguished for the highest professional knowledge and success.

Such being the case, a certain leadership belongs to this Society, which cannot be refused. It is expected—in a sense demanded of us. The position is ours, and its responsibilities cannot be properly ignored; nor can the duties of such leadership be safely neglected. It belongs to this Society to take the initiative in the correction of abuses where discovered, and in the introduction of real improvements.

## MORAL EQUITY AS BETWEEN PROFESSIONAL BRETHREN.

To this end you will permit a question or two, not inappropriate to the occasion, and which I heartily commend to your good judgment and enlightened professional conscience. My first point is not so much a question of legal justice, but rather a matter of moral equity as between professional brethren, and especially as between two classes with unequal opportunities and rewards. Of course it belongs to us to lead the medical profession in the adoption of all measures calculated to secure to every member full legal rights; but quite beyond this, I think it will be conceded, that upon the more favored and successful practitioner rests a special moral obligation to see that no procedure of his works an injustice, or is occasion of needless embarrassment to his less fortunate brethren. I am satisfied that such injustice and embarrassment is occasioned by the readiness of the communities to abuse opportunities for free treatments, together with the indifference of many physicians, and their failure to investigate and to discriminate in such cases. It is not my thought to check a real benevolence. I would be the last man to deny the reliefs and benefits of science to the poor. It is a glory of this city, that no one, in whatever extremity of poverty, needs to perish or suffer for lack of prompt and skilful medical attention. But the policy, or at least the practice, of many dispensaries and hospital associations, puts a premium on meanness; and withdraws from the local practitioner his natural clientage, by compliantly serving at the free dispensary those who are abundantly able to pay for what they receive. Not only so, but to appease an uneasy conscience, a nominal fee is asked and given, and further moral obligations are lost to view. This is in fact abetting fraud. It is an outrage upon public confidence, as well as a very palpable injury to a large class of practitioners. Our leading physicians and surgeons connected with these charitable institutions are more or less responsible for this state of things. We freely admit that the case presents some difficulties, but surely new rules, or more conscience, care and discrimination are demanded. A most public and flagrant instance is furnished by the Board of Health in its recent crusades of wholesale vaccination. There is, perhaps, little to be said of the work in Cherry street and the like; but when it comes to the free vaccination of the employes of prosperous business houses and rich corporations, and even of the sleek moneyed men of the Produce, the solidated, and the Stock Exchanges, and

* Inaugural address before the Medical Society of the County of New York, by the President.

the Board of Trade, the preposterous extent of the abuse and the consequent professional injury in seen at a glance. Such things could not occur did not physicians lend themselves to the scheme. I should prefer to believe it was done thoughtlessly; and I trust that a declaration on the subject by this Society would do much toward correcting such abuses.

Again, whenever a man puts a low estimate on the importance and value of his own service, he so far lowers the medical standard, and thereby injures his professional brethren. Why reputable physicians should consent to serve rich corporations for nominal returns, would seem hard to explain. But the anomaly exists. Many illustrative instances of these misplaced favors will occur to the minds of these present. In this regard the legal profession sets us a different example, and one worthy of our emulation. So far from belittling the importance of his own service to the injury of his own profession, the corporation lawyer exacts the highest fees, and those commensurate with the interests involved. Why should the physician adopt an opposite course?

### ON EXPERT MEDICAL TESTIMONY.

Another point to which I would call your attention is the matter of expert medical testimony in the courts. Comparatively recent events in connection with some trials of peculiar public interest have given this subject especial prominence. My impression is that the result has been to discredit the value of the expert testimony as a whole. It is evident that in the case of conflict or apparent discrepancies between the testimonies of reputed experts, neither the public, the ordinary jury, nor indeed the bench of judges, nor the bar, have the especial training which would qualify them to discrimate between true and false, and duly to estimate the scientific value and the proper influence of the facts in a given case. The result is to create an impression of vagueness, a natural distrust of the whole business, and of the medical science with which it is associated. Such a matter at first thought might seem beyond the power, if not the province of this Society. But permit me to suggest that it is not really so. Both in the interest of civil justice, and of our profession, the evil might be rectified by the appointment from this Society of a commission or jury of competent physicians to review and to pronounce upon the entire expert testimony in each given case. The summing up by such a commission would in the highest degree inspire confidence and subserve the ends of justice. Of course such a procedure must be authorized by Statute law. But it is entirely within the province of this most influential body to propose and to secure the appropriate legislation.

### ON MEDICAL LEGISLATION.

And this brings me to another very important consideration affecting our relation to the profession at large, the State and the community. It is an undeniable principle that with a responsibility of any sort must go the power and supervision in the matter under consideration. Now since this is the legally instituted and recognized medical society of the County of New York, and the body in which inheres the major responsibility for whatever action may be taken affecting medical affairs, it follows that all legislation relating to the practice of medicine, either as between physicians, or between the physician and the community, should be first admitted to this Society and receive its approval or disapproval before it is transmitted to the State Society or proposed for enactment as a law. A Society of such a character as this is often asked to endorse plans and schemes which may be worthy of its endorsement, or possibly should not receive its sanction. In my judgment *all* such propositions should be referred to the *Comita Minora* for careful consideration before any official action is taken, and I so recommend.

In view of all that has been said upon this subject and of the necessities of the case, the propriety must be manifest to everyone of adding to our standing Committees one on Legislation, to the especial care of which may be committed all such matters, often among the most important upon which we may be called to take action.

### A CASE OF OFFICIAL DISCOURTESY.

A recent case of official discourtesy and injustice I think worthy of mention in this place, not so much on account of its intrinsic character, as in view of what appears to me a want of proper *espirit de*

*corps* and professional sympathy in the treatment of the affair by some of our physicians: Referring to the case of the New York Infant Asylum, it is noted in the issue of the *Medical Record* of November 25th that, "A recent attempt to bring before the medical profession the question of the treatment of Medical Boards by the managers of hospitals, provoked unfortunately, a somewhat sharp discussion at the Academy, and showed again how quickly a number of physicians will side with the higher and the moneyed powers and against their medical brethren."

The facts of the case entirely justify the remark, which I have quoted from the *Journal*. It is indeed an unfortunate state of affairs, not that the atmosphere of the Academy should be stirred by a sharp discussion, but that physicians should be so short-sighted, not to say partial and unjust, as to range themselves upon the wrong side of such a controversy. By all accounts the course of the Board of Managers was arbitrary, ungrateful and discourteous in the extreme to the Board of Physicians, who had long given the institution without reward, and as it now appears without thanks, a valuable service in the frequent rendering of their professional care, and by their advice as to competent men for visiting physicians. Upon what ground such discourtesy to such men can be justified it is hard to see. But my especial point is, that, is if we do not sustain honorable brethren of our own profession in their expectation of just and courteous treatment, we injure and degrade the profession itself. A certain jealousy for professional rights and honor is certainly due from every member of the fraternity; and every failure in this regard not only reacts upon ourselves, but is an injury to all.

SECTARIAN DESIGNATION.

Perhaps a mere allusion may not be out of place to the attitude of some, who are not unwilling, to say the least, that an impression should go abroad that they are practitioners of sectarian medicine. If a word to the wise is sufficient, it should only be necessary to recall the positive attitude of our Society upon this subject, and its unmistakable declarations. Article XVII of our Constitution reads: "No member of this Society shall assume any sectarian designation indicating that his practice is based on any special doctrine or dogma, or specified method of treatment." And again, the closing sentence in the form of application for membership reads: "And (I) hereby declare my abnegation of sectarian principles and practice." The moderate and conservative thought is, that the County Society means just what it so emphatically proclaims, and that the only proper and just course is to receive gentlemen as members, when all the requirements for membership are complied with.

ON INCREASE OF MEMBERSHIP.

In closing let me express some sense of the pleasure and profit personally derived from my connection with this Society in the past, and my desire for its present and future importance and usefulness. To this end I ask that the present members have in mind the thought of increasing our membership by the introduction of proper candidates; and that from the older members especial consideration be shown for the young men of the profession, both within and without the Society. Such encouragement is often of great value to the recipients, and the young blood is essential to the health and growth of the organization.

I further crave your consideration and assistance in my efforts to facilitate the business and to promote the interests of this body in the honorable and responsible position in which you have placed me.

---

**Purpura of the Newborn.**

Glenn (*Transactions of the Royal Academy of Medicine*) reports the case of a first child of healthy parents; no history of syphilis, child asphyxiated when born. At birth the infant was covered with discrete hemorrhagic spots, especially on the face, chest, and back. On auscultation a loud bruit was heard over tricuspid area. The child lived thirty-six hours. On post-mortem the spleen was found much enlarged and of a deep red color, weighing forty-five grammes. Liver enlarged, deeply stained with bile and firm to the touch. Kidneys, with the exception of a few superficial hemorrhages, were normal. Stomach and intestines were covered with purpuric spots similar to those on the skin. Both visceral and parietal layers of the pleura were studded with hemorrhages, the same condition being found in the pericardium. Foramen ovale open. All the remaining internal organs were hemorrhagic.—Ex.

# EXCISION IN THE TREATMENT OF SPINA BIFIDA.*

JOHN B. ROBERTS, A. M., M. D., PHILADELPHIA.

The unsatisfactory results which are believed to follow operative treatment of spina bifida have induced the profession to largely refrain from active measures in the management of the condition. A most conservative view is found in *Stephen Smith's Operative Surgery*, which the author attributes to Holmes, but seems to fully endorse. He says: "No case of spina bifida ought ever to be subjected to any active operative interference, except in the most urgent circumstances, and the mildest measure which affords any rational prospect of cure should be the one selected."[1]

The Committee of the London Clinical Society, consisting of Messrs. Howard Marsh, A. Pearce Gould, H. H. Clutton, and Robert William Parker reported in 1885 "That the evidence was conclusive that a large proportion of specimens of spina bifida the spinal cord is within the sac;" and that the committee was not acquainted with any means by which it was possible to determine in the living subject that the spinal cord was not in the sac. For this reason the committee believed "that any operation involving interference or removal of the *median vertical portion* of the tumor should be entirely abandoned." This statement was made notwithstanding the fact that the members of the committee were "quite conscious of the large measure of success that has attended the operations of ligature and excision, but we cannot lose sight of the fact that these operations always expose the patient to the grave dangers attending removal of the expanded spinal cord and attached nerves." After an extended examination of specimens and of the literature of the subject, this committee came to the conclusion that the plan of treatment by injection with iodine, iodide of potassium and glycerin, recommended by Morton, was the best with which its members were acquainted, and was the only one which they felt justified in recommending.[2]

Cabot at a recent meeting of the American Surgical Association states[3] that Treves is of the opinion that operative treatment of bifid spine "can only be undertaken in those comparatively infrequent cases where the sac is quite free from either the cord or any of the spinal nerves," and that "if the sac contains cord elements, result will prove fatal." J. William White wrote, in 1891, that he believed that most surgeons agreed with the opinion that injection with the iodo-glycerin solution is the best method of treatment.[4]

It is not surprising that such expressions as those should have deterred surgeons from attempting excision in spina bifida. It is because I find myself obliged to dissent from these opinions that I recently operated upon a case which I desire to record. A consideration of the circumstances surrounding the fatal issue of my own case and the study of surgical literature have pretty thoroughly convinced me that in properly selected cases excision is not only justifiable, but will be found satisfactory in relieving the patient from the disability due to the congenital defect.

The importance of undertaking active treatment in bifid spine is shown by the record of 647 deaths from this congenital condition in England in the year 1882. Of these deaths 615 occurred while the patients were under one year of age.[5] The fatality of the affection is well illustrated by this record, and is a piece of evidence whose value is not broken by the 13 cases of spontaneous cure found by the London Clinical Society Committee after a laborious search in surgical literature.

Occasionally patients with spina bifida may reach adult life, as in the unusual patient mentioned by Callender, who had attained the age of seventy-four years.[6] The Clinical Society Committee found 13 cases, who were living at, or who had, before death, attained ages varying from nine to forty-three years. Mr. Clutton operated successfully by excision on a lady aged twenty-four years.[7]

7 Sajous' Annual of Universal Medical Sciences, 1892, p. A. 50, from London Lancet, October 10, 1891.

These unusual instances of longevity, notwithstanding the existence of such a perilous condition, do not invalidate the evidence of the great infantile mortality shown by the statistics in England alone during 1882. From what I have said it would seem that the two methods which the surgeon should contrast are injection by the iodo-glycerin solution and excision. The Clinical Society Committee collected 71 cases treated by this injection; of these 35 had recovered, 27 had died, 4 were relieved, and 5 were unrelieved. Dr. Morton, the advocate of this injecting material, had informed the committee that of 50 cases so treated 41 seemed to have been successful. I presume that some of the cases in the two lists were the same patients. The same committee collected reports of 23 patients treated by excision of the sac, of whom 16 recovered and 7 died. Ashhurst states[8] that the statistics collected by that committee and by Dr. C. A. Powers show that of 86 cases treated by the injection method, 50 were benefitted, and of the 57 cases treated by excision, 40 cures resulted. Dr. Powers' paper is well worth careful reading, and will be found in the *Medical Record*, July 16, 1892.

The injection of the sac seems to me so unscientific, because it is really groping in the dark, that I am impelled to the conclusion that incision,exposing the contents of the sac, followed probably by excision, is the preferable method of dealing with bifid spine. This conclusion is confirmed by the results attained by myself and others in many operations upon the brain and spinal cord. An aseptic wound of these organs, under ordinary circumstances, seems to be comparatively safe. Operative treatment, therefore, of spina bifida under modern methods must be considered in a rather different light from that of five or six years ago. I agree almost perfectly with those who consider excision a satisfactory and proper operation, even though it be undertaken in children but a few weeks or months old. Various modifications have been proposed in the endeaver to remove the tumor and close the fissure in the vertebral canal.

Two cases are reported by the Committee of the Clinical Society in which the skin was dissected from the sac and then sutured in the middle line over the tumor. I do not know of this method of operation being performed by others than the two operators mentioned in the report. Death occurred in one case, recovery in the other.

Evacuation of the fluid and excision of the sac of the tumor is the method usually meant when excision is mentioned. The dura should be divided and stitched so that the line of suturing does not correspond with the suture line in the skin. This method is especially advocated by Mayo-Robson.[9] Mr. Mayo-Robson in one case inserted a portion of periosteum, taken from a rabbit, over the closed meninges; and carefully sutured it to the periosteum of the laminæ on each side of the cleft. No bony formation resulted from this transplantation, though the periosteum taken from the rabbit evidently preserved its vitality. In one of his cases, cure was accomplished even after suppuration had occurred in the sac. The operation consisted in complete removal of the sac with efficient drainage. Of the four cases operated upon by him, three recovered. This operator also suggested bending the neural arches toward the middle line and uniting them with silver wire in the endeaver to make a bony wall to the defective spinal canal.

Osteoplastic operations similiar to the method proposed by Mayo-Robson, but not used by him, have been performed successfully by J. Dollinger,[10] of Buda Pest, by Zenenko,[11] of St. Petersburg, and by Rochet.[12] Berger[13] operated successfully on a child seven weeks old, by transplanting a piece of the scapula of a rabbit, and Bobroff,[14] performed an osteoplastic operation, taking a section of bone from the crest of the ilium of the patient to fill the gap in the sacrum.

Rochet states that the structures resembling nerves traversing the sac are not always true nerves and have no physiological function. They can be cut or exercised without special harm being done to the patient. He says that Bellange reports 11 cases in which nerve filaments of various sizes were cut during operations without any paralytic or anæsthetic phenomena resulting. This observation made my other observers is said to be the rule.

14 Annals of Surgery, September, 1892, p. 270.

The securing of a vertebral canal by some osteoplastic procedure would seem to be a very desirable addition to the original operation by excision. I do not know how much better the condition of the patient is, however, after such attempts at securing a bony closure of the gap. Theoretically, it would seem desirable, but many cases have been satisfactorily cured by operation, in which removal of the sac and simple suturing of the skin over the gap in the bone were done. The bone to be used for closing the gap may be obtained as in the operations recorded, or, as suggested by Bobroff, from one of the ribs when the bifid spine exists in the dorsal region. De Ruyter, of the University Clinic at Berlin, has made an interesting study of the question of excision in the condition under consideration.[15] He believes that cases of meningocele are usually proper ones for operation, but of meningomyelocele, only those are suitable for operation in which the proportion of the essential elements of the cord involved in the cyst wall is small and derived from a point below the sacral plexus. He excludes from operation all cases of this class in which the nerves given off from the spinal cord, lying in the median line, pass to the cyst wall and thence to the inter-vertebral foramina. He also excludes from operation all cases of myelocystocele because these cysts are usually small, the skin covering them sound, and the patient's condition about as good as it would be after operation. He gives some suggestions for diagnosticating these varieties of spina bifida, and considers a puncture or exploratory incision justifiable for diagnostic investigation previous to operation. Of eight cases treated by surgical operation in the Berlin Clinic during the time over which his study extended, five died.

Hildebrand, of Göttingen, at the meeting of the German Surgical Society this year, presented a careful study of 27 cases of bifid spine and showed that the cleft may involve the bone, dura pia, cord and the over-lying soft parts, or only one or two of these structures. He reports 13 cases operated upon in the Göttingen Clinic, of whom 10 were discharged cured. He advocates operation on all varieties of spina bifida, excluding only those in which there is a marked degree of paralysis.

I have made no attempt to collect cases of bifid spine treated by excision. The operation has probably not been done very often in America. Cabot,[16] of Boston, Hayes,[17] of Rochester, and Hurd[18] have reported cases. I add the clinical record of a case recently operated upon by me which terminated fatally.

A male child, fifteen days old, was seen by me on September 25, 1893, at the request of Dr. Isaac W. Hughes. The child was exceedingly healthy and well formed, except a bifid spine. The prepuce was, however, adherent, though no true phimosis existed. One of the legs showed some lack of power, but their sensation I did not test. The contents of the rectum and bladder were evacuated at ordinary intervals, though according to the statement of the nurse, there was a tendency to dribbling of urine nearly all the time, and some slight leakage from the rectum when the baby strained. It is possible that thsee were evidence of a want of control of the sphincter due to condition of the spine. The infant nursed well and cried very little, showing its extremely healthy and comfortable condition. The tumor due to the congenital deformity occupied the upper portion of the sacrum. It was hemispherical and measured about an inch and a half vertically and horizontally, and was elevated above the surface of the back about one inch. The central portion consisted of translucent tissue upon which was an ulcerated-looking space toward the lower portion of the tumor. This granular or ulcerated condition was present at the time of birth. The normal skin extended up the tumor on each side to a sufficient extent to leave only about half the surface of the hemispherical swelling of translucent tissue. The mass fluctuated on pressure and seemed to increase little, if any, when the child cried. Under the circumference of the tumor on each side could be felt a hard edge which seemed almost like bone, but which was evidently the margin of the muscles of the back or the posterior border of the iliac bone on each side.

15. Annals of Surgery, September, 1890, p. 296.

16 Annals of Surgery, August, 1892, p. 121.

17 Ashhurst's Principles and Practice of Surgery Ed. of 1893 p. 720.

18 Therapeutic Gazette, October 1, 1889.

The parents of the child were given an unfavorable prognosis and an operation by excision advised. Accordingly, I cut away the mass on Wednesday, September 27, 1893. Corrosive sublimate solution was used for the sponges and for sterilizing the surface of the child, but the instruments were kept in betanaphthol solution after having been sterilized by heat. Ether was used as the anæsthetic.

A puncture was made on the right side of the tumor above the margin of the skin, and about two drachms of colorless fluid allowed to escape. No symptoms occurred during this evacuation of cerebro-spinal fluid. The collapsed sac was then excised by two curved incisions meeting at a point above and below the protrusion in healthy skin. Six or eight nerves were found attached to the internal surface of the translucent membrane forming the dome of the tumor. These were consequently dissected loose as close to the membrane as possible. On each side of the sacrum in front were seen similar nerves, but of larger size, entering the anterior sacral foramina. These, as well as the nerves dissected from the sac, came out of an opening at the upper portion of the sacrum which led to the vertebral canal. This opening would not entirely admit the tip of my little finger and was circular, being about three-eights of an inch in diameter. In this opening lay what I supposed to be the cauda equina, which very nearly filled the entire orifice. This bony opening was situated very close to the upper edge of the external tumor, which had been developed principally below the opening rather than over it. The dura mater was apparently adherent to the internal surface of the tumor wall. The posterior wall of the vertebral canal in the sacral region was absent below the opening mentioned. The anterior sacral nerves were not interfered with, but the posterior ones with the cauda equina, or lower end of the cord, were pushed into, but not through the bony opening by my finger tip. The youth of the child and the serious character of the operation deterred me from undertaking an osteoplastic procedure, and even from interfering with the contents of the sacral opening.

The skin flaps left by the incision of the sac were then brought together over the site of operation by interrupted catgut sutures. No drainage was used and the wound was sealed by strips of gauze saturated with iodoform and collodion. Some slight bleeding had occurred, but it was controlled without difficulty, and the sutures were applied so as to catch the vessels which seemed likely to bleed. A large mass of carbolized gauze was then applied and firmly held in place by a bandage. No ligatures had been required. The child slept after the operation and seemed to be reacting well.

The operation was completed about 3 P. M., having occupied about half an hour. In the neighborhood of five o'clock that same afternoon the nurse noticed some blood escaping from under the bandage. Attemps were made to stop this blood by pressure, without removing the dressing, but they were unsuccessful. At half-past nine I saw the child and removed the dressing, discovering that the bleeding came from a point at the upper angle of the wound, where pressure of the dressing was probably not as efficient as over the rest of the operative field. An acupressure pin was thrust through both margins of the wound and a catgut ligature wrapped around the ends of the pin in an eliptical manner. This readily stopped the bleeding. A similar pin was put at the lower angle of the wound as a precautionary measure, though it was not sure that any part of the bleeding came from that point. The upper pin was situated over the spot where the cauda equina had been pushed into the spinal opening, but was so inserted that no injury to the cauda or spinal nerves could occur. An iodoform and collodion dressing was again applied, and carbolized gauze adjusted outside of it. It is probable that the patient lost about an ounce of blood. Its lips, however, and finger tips retained their pink color, though the child looked paler than before the original operation.

I observed that the acupressure pins inserted deeply in the muscles of the back gave the baby no pain though this procedure was done without anæsthesia. It was evident, therefore, that there was a defect in the innervation of this region, as would be supposed from the nature of the congenital lesion.

Three drops of whiskey were administered about five times during the succeeding night and the following day. After the redressing the patient seemed quite

comfortable and needed no anodyne; and indeed none had been required previously. It slept comfortably, continued to nurse well, and seemed hungry.

The morning after the operation, at about 10 o'clock, the nurse observed evidences of nervous irritation shown by the head being bent backward, and some irregular muscular action of the eyes. The arms and legs, however, did not become stiff, and the baby did not cry or seem to feel pain. It, however, was very apt to start at sounds and had to be removed from a room in which a wood fire was burning, because the crackling of the wood thus annoyed it.

I saw the patient again at 5 P. M., having left in the morning about eight, before the symptoms of nervous irritation had shown themselves. Up to that time it had had eight or nine spasmodic attacks of the kind mentioned, and had taken since noon about three grains of potassium bromide in doses of one grain. This had been prescribed by Dr. Donnel Hughes, because of the evidences of nervous excitement. The nurse reported that the spasms had been less marked since the bromide mixture had been taken. Since morning the baby had refused to nurse, but had been fed with breast milk by means of a spoon. During my visit I had opportunity to observe one of these convulsive seizures. The head was quite strongly retracted by spasms of the posterior cervical muscles; the occipito-frontal muscle caused tranverse furrows in the forehead, and the ocular muscles produced by their spasmodic action an irregular and varying strabismus. There appeared to be no spasm of the extremities and no real pain, for the child did not cry.

Before the occurrence of this seizure its pulse was 160 and not very weak; its respiration 60, and its temperature in the rectum 99.8° The whiskey which it had been taking during the day, as previously detailed, was stopped, and the bromide mixture increased so that it received two grains every two hours unless asleep. No further hemorrhage had occurred.

Thursday night, September 28th, pulse, 116; respiration, 60; temperature, 98.4°. Friday morning, September 29th, pulse, 130; respiration, 59; temperature, 98.1°. The attacks of spasm ceased about 7 o'clock last evening, and were even before that time not severe. At 4 P. M. there had been no further seisures, the child had taken its medicine and milk, which had been given with a spoon, and had a good movement of the bowels. The leakage from the bowel, which had previous to the operation been almost continuous, had ceased. The baby had been taking two grains of potassium bromide every two hours during the night and to-day, and had slept well. Friday evening, pulse, 136; respiration, 52; temperature, 97.6°.

On the morning of the third day after the operation, at 2 A. M., the child had a general convulsion which was followed by four others within two hours. The arms and legs became rigid, the gums were tightly clinched, the head drawn back, and the child's face cyanosed. The spasm seemed to involve all the muscles of the trunk, and even those of the scalp and face. One grain of potassium bromide was given every hour. After a few doses the convulsions diminished in frequency and severity. A slight one occurred about half-past seven, when no bromide had been taken for about two hours. The bromide was ordered to be continued, one grain every one or two hours according to the condition of the patient; and inhalation of one drop of chloroform directed to be administered if the convulsions were prolonged or frequent. The bandage was removed; the iodoform dressing opened immediately over the head of each of the acupressure pins, and these pins were withdrawn. The small hole made in the dressing was closed with absorbent cotton sealed with iodoform and collodion. A drop of brown blood oozed through the original dressing at the spot where the upper pin's point was situated. There was no evidence of sepsis and the original dressing was unsoiled and sealed the wound thoroughly. There was no escape or oozing of cerebro-spinal fluid observable at any time during the after-treatment of the case. The temperature at this time was 98.6°; pulse, 140; respiration, 46.

On the fourth day after operation I noticed oozing of some brownish fluid from under the lower part of the dressing near the gluteal crease. At this time the child had had no convulsion for thirty hours. Fearing that the proximity of the lower portion of the dressing to the

anus would lead to contamination of the wound by the escaping fluid becoming infected, I removed the iodoform and collodion dressing, which had been applied on the evening of the operation at the time I introduced the acupressure pins to stop hemorrhage. The wound was healed by first intention, except at the upper end, where there was a small gaping of the skin and a granulating surface. Across the upper and lower portions of the wound were lines of devitalized skin, rather grayish in color, evidently due to the acupressure. No cerebro-spinal fluid was escaping at any point. I was quite certain that the tissue which had been compressed by the acupressure pins would slough, but the rest of the wound seemed so healthy that I thought I should have little trouble with further local treatment. The wound was dressed with bichloride gauze after having been dusted with boric acid powder.

The dressing thereafter was changed daily. The wound however, did not do well. After the slough caused by the acupressure pins had separated, and on the twelfth day after operation secondary hemorrhage occured from the upper part of the wound at very much the same spot from which the original hemorrhage had occured a few hours after operation. This was treated by pressure and a new dressing. Two days later it recurred and was controlled by the introduction of two catgut sutures introduced at the point of bleeding. Death occurred fifteen days after operation from exhaustion due to the hemorrhage and the septic contamination from the sloughing surface. No autopsy was obtained.

The unfortunate result in this case was almost certainly due to infection of the wound occurring during the operation or at the time or the removal of the iodoform and collodion dressing on the fourth day. At that time, as has been stated, the wound was completely united. I noticed, however, a drop of purulent-looking fluid at the opening made by one of the catgut stitches.

Whether this catgut, which I had not prepared myself, was septic, and acted as the original focus of suppuration and sloughing, I am not able to say. It is possible that in many changes of dressing some fault in technique may have happened, as on one or two occasions the dressing had to be made under difficulties. The imperfect nerve supply of the part is to be taken into consideration as a cause of lessened resistance in the tissues when sloughing and suppuration once began. I have also thought that it possibly was an error to have used boric acid powder upon the wound daily, as the irritation of this drug may have aided in devitalizing the tissues already defective in nerve supply. I used the boric acid powder because I feared that otherwise the wound not be kept dry; and that if moist, infection by fecus or urine would more readily occur to vitiate the result. Until the secondary hemorrhage took place, I thought that the patient was on the road to recovery, although his temperature was rather high and irregular, on account of the sloughing process going on in the back. He took food well, seemed comfortable, and had very few convulsive seizures, which seemed to be easily controlled by bromide of potassium internally and chloroform inhalations.

---

**Danger From the External Use of Salicylic Acid.**

The *Schweizer Wochenschrift fur Pharmacie,* publishes the following: a few days ago, one of our country practitioners, who had long been troubled with sciatica, concluded to make a trial in his own case of salicylic acid, in alcoholic solution, as recently recommended for rheumatism. He applied compresses dipped in the liquid, renewed them several times in the course of the evening, and was getting ready for bed, when he was suddenly attacked by a feeling of general distress, violent itching, and roaring in the ears, then began to swell up, and finally lost consciousness. His family thought he was dying. A colleague who was hastily summoned found him enormously distended all over (as if by inflation of air) and profoundly comatose. A large dose of salicylic acid had been taken through the skin. Under the vigorous administration of stimulants and purgatives the patient revived; the swelling subsided, and in a few days he was able to be about. Salicylic acid ointment may also give rise to serious symptoms, as I have had the opportunity of observing in several cases. A single application is sometimes followed by such a degree of swelling and inflammation that the remedy has to be discontinued. These facts should operate as a warning to pharmacists, never to dispense salicylic acid except on a doctor's prescription."

# TRANSLATIONS.*

## CARCINOMA AND ENDOTHELIOMA OF THE OVARY.

Dr. Vitalis Müller studied microscopically six ovarian tumors under the direct instructions of von Recklinghausen. The tumors appeared to belong to the above mentioned varieties.

Two primary carcinomas seemed to have originated in the Graafian follicles. One of secondary origin, whose primary seat had been in the uterus, appeared to have followed the lymph channels along the periphery of the ovarian peritoneal covering. These conditions can be explained only by accepting the theory of von Recklinghausen on "retrograde embolie." In a case of primary carcinoma of the supra-renal capsule, the epithelium of the ovarian stroma was found intimately connected with tubules lined with endothelium, and there seemed no reason to doubt that a secondary attack would have located itself in the ovary. Another tumor, belonging no doubt to the proliferating glandular variety, presented in the cyst wall epithelial layers anastomosing with each other and the lymph channels, producing the characteristic nodule. In the last case which belonged to the endothelial variety, the initial points being located in the wall of a glandular cystoma —it had originally been a multilocular cyst about the size of a child's head—the inner surface was lined by a cylindrical epithelium with an ovoid nucleus. In the wall hollow spaces could be seen lined also with the cylindrical epithelium. Close to these glandular hollow spaces, a united tubular system existed, which was lined with cubical epithelial cells. At various spots these hollow spaces were surrounded by hyaline tissue degenerating into epithelial elements; in others papillomatous degeneration could be seen.

Careful examination of the last four cases led to the following conclusions.

1. If epithelial cells have entered into and multiply along the blood and lymph channels, a histological picture presents itself, which, in many cases, cannot be distinguished from an endothelioma of the ovary.

2. Intra-canalicular papillomatous formation following the course of the lumen of blood vessels, has not been heretofore observed in undisputed cases of cancer. No differential diagnosis can therefore be made in doubtful cases, unless a careful study under the microscope has preceded it.—*Arch. f. Gynaekol. bd II.*

## OPERATIVE TREATMENT FOR TUBERCULAR PERITONITIS IN CHILDREN.

The author (L. Conitzer), reports seven cases, four belonging to the exudative and three to the dry form. All were operated upon at the Jewish Hospital in Hamburg. The histories and results are given in detail, and the author presents the following conclusions:

1. Tubercular peritonitis can be cured spontaneously in the dry form comparatively less frequently than in the exudative type, which is cured in most cases.

2. The spontaneous cures of the exudative form of tubercular peritonitis, have heretofore been regarded as cases of chronic exudative peritonitis or ascites.

3. All forms of tubercular peritonitis can be cured or at least improved by abdominal section, even though other therapeutic measures, including puncture, have been tried previously.

4. The result of the operation depends upon the form of the disease, (the best results being attained in the chronic variety), the previous duration of the disease and the eventual complications.

5. The operation is indicated when the internal therapeutics have proved of no avail.

6. The operation is contra-indicated in those patients of poor vitality, or in cases suffering from tuberculosis of other organs.

7. The question of how the cure is effected by abdominal section in these cases, has remained unanswered.—*Deutch. Med. Woch.*

## ANATOMICAL CONSTRUCTION OF SOME OF THE GRANULAR SWELLINGS OF THE INTEGUMENT.

L. Philippson, (*Central. f. Allgem. Path. u. Path. Anat.* IV., 1893), has directed his studies to the modus operandi of infection, whether internal or external. His observations embraced chiefly syphilis, leprosy and tuberculosis. His studies resolved themselves into the following conclusions:

I. *Infection Externally.* First, syphilitic sclerosis; second, the superficial lepra nodes (?) found in the papillary layer surrounded by healthy tissue; third, superficial lupus nodes. These are all new growths, situated superficially, having sharp lines of demarcation, more or less round or concentric in form; the deeper structures are attacked later in the course of the disease.

II. *Infection Arising through the Circulation.* First, roseola, syphilitic papules; second, acute erythematous spots or papules of lepra; third, efflorescence in miliary tuberculosis(?). These new growths at the onset extend in their development throughout all the layers of the cutis and follow along the ramifications of the blood-vessels.

III. *Infection through the Lymph Channels* First, superficial nodes of leprosy developed above the cutis (?); second, miliary lupus originating from deep-seated infections.

The new growths of the third group, which may also belong to the syphilitic or leprous type, cannot be distinguished by any regular appearance, and are rather flexiform in character.—*Schmidt's Jahr.* —W.

### Prophylaxus of Puerperal Diseases.

R. Frommel (*Deutsch. Med. Woch.*, No. 10, 1892), says that from April 1, 1887, to November 15, 1890, of 559 women confined, one died of puerperal fever.

Disinfection of the genitalia, after liberal use of soap and water, was effected by a solution of bichloride 1: 2000; the cervical canal also being carefully cleansed with the same.

From November 15, 1890, to December 11, 1891, there were 197 obstetric cases, in whom the external disinfection alone was used. Of these, 3 died of puerperal fever, and the percentage of those who were ill ran as high as 11.1. As a result of these observations, the author desires to emphasize the importance of external and internal antisepsis, as also that of personal cleanliness.—*Schmidt's Jahr.* —W.

### Spelling Made Hideous.

The *Medical Press and Circular* prints the following Philistine editorial: "Many of the American medical journals are now becoming so hideous in the matter of spelling that it is a difficult matter even for an ordinary educated English medical man to read them without wishing to throw up his task in disgust. The van of this insane effort to appear novel is led by the Philadelphia *Medical News*, and now we learn that the editor of that journal is bringing out a new edition of a 'Medical Dictionary of Terms,' in which all this ne-fangled and absurd method of spelling will be incorporated. The rising generation of young American medicos are to be pitied if they are required to adopt the teaching in orthography which will obtain in this 'Dictionary.' We are glad to see that some of our leading contemporaries in the United States have not been led into disfiguring their columns by such words as 'chemic,' 'bromid,' and 'physiologic,' together with others equally absurd and hideous. The introducer of this *fin de siecle* method of spelling affirms that no argument can be advanced against it. But what about the rules of grammar and prosody so far as the English language is concerned. Perhaps under the circumstances it would be best at once to bring out a book dealing with the subject of 'The American Language: its Grammar and Orthography,' and then there would be no difficulty in showing that the American method of spelling had nothing to do with the English language."

# THE MEDICAL AND SURGICAL REPORTER

ISSUED EVERY SATURDAY

Address care P. O. Box 843, Philadelphia, Pa.

HAROLD H. KYNETT, A. M., M. D.
Editor

RODERIC C. PENFIELD
Publisher

147-149-151 North Tenth Street, Philadelphia

**TERMS:**—Three Dollars a year, strictly in advance. Sent four months on trial for $1.00.

**REMITTANCES** should be made payable only to the Publisher, and should be made by Postal Note, Money Order or Registered Letter.

**NOTICE TO CONTRIBUTORS:**—We are always glad to receive articles of value to the profession, and when used they will be paid for, or reprints supplied, as the author may elect. Where reprints are desired, writers are requested to make a note of that fact on the first page of the MS. It is well for contributors to enclose stamps for postage, that the articles may be returned if not found available.

SATURDAY, JANUARY 6, 1894.

## EDITORIAL.

### PROSPECTIVE.

Entering upon this its forty-second year of continuous publication, the REPORTER sends greeting to the medical profession at large and to its friends and supporters, both old and new.

To its old friends but few words are necessary. You have appreciated and cordially acknowledged the REPORTER'S untiring efforts to present to you what is latest and best in the medical world, avoiding discussions of abstruse matters and giving practical information that can be made use of in your every-day work.

It is utterly impossible to bring into the pages of any one journal the complete records of current medicine, but the entire field of medical science has been carefully and thoughtfully considered by the REPORTER and only the best and most useful of all available material brought under your notice.

The change that will appear most striking to you just now, is the reduction of the subscription price from five dollars to three dollars per annum. There will be no other radical change in the journal, but a continuous, steady improvement will be made as opportunities may offer. Paid-up subscriptions for 1894 at the old rate, made before the change was announced, will cover proportionately greater time, and paid-up subscriptions at the old rate, beginning in 1893, but extending into the year 1894, will also be extended proportionately from the beginning of this year.

To our new friends it may be well to briefly state by way of introduction, that the MEDICAL AND SURGICAL REPORTER was among the very first of medical weekly journals to be established in America. Its continuous existence is sufficient evidence of its value to the medical world, and its large clientele demonstrates its influence and progressiveness. The journal has experienced the ups and downs common to journalistic existence—save that most common, failure,—and now, in its forty-second year, is in the prime of its life and influence.

It is not at all unusual, and is a most encouraging incident, for the REPORTER to receive from its older subscribers, who

have taken the journal continuously for years, congratulations on the maintained excellence of quality, independent attitude and progressive spirit displayed by it, together with the statement that the journal is better to-day than it has ever been.

You will expect to find the REPORTER a journal for the busy, every-day doctor. You will find in every issue something, at least, that will be of immediate service to you in your daily work. Its pages rarely contain lengthy technical discussions of abstruse subjects, however valuable to medical science in the abstract. There is not sufficient room, and there are other journals, more properly keeping these records. The physician in active practice, must have his facts presented to him tersely and pointedly. His munitions must be given him ready for use in the field. He has little disposition and no time for theorizing, experimenting or manufacturing. As he deals with human life, and recognizes his responsibility, he demands that his informant be trustworthy, and his information authentic. He will not risk life on the strength of hearsay, nor the assurances of advertising testimonials. The REPORTER brings him the best thoughts and experiences of the best minds in the profession, presented in a form readily apprehended and easily remembered.

As the progressive physician enlarges his knowledge and increases his success by studying the work of other men, it is his duty to his profession to allow others the benefit of his work and thought. There is no physician worthy of the name who cannot suggest something of value to others of the profession, and thus aid to advance the interests of his calling. The REPORTER desires to present such benefits to the medical world.

Again the MEDICAL AND SURGICAL REPORTER is a journal for the general practitioner. It cannot cover in detail the work done in all of the numerous specialties, but, to give as wide a view as possible, the department of *Current Literature Reviewed* was established, and here will be found in briefest form to be intelligible, the most valuable articles contained in literature devoted to specialties. This review was a new departure in medical journalism and its value was so promptly recognized that many other journals have established similar departments.

In the *Library Table* will be found notices of the most valuable recent medical books, and reviews of these works at the hands of competent and unbiased reviewers, made entirely in the interests of the readers of the REPORTER.

The reports of foreign work are taken directly from foreign journals, and translated especially for the MEDICAL AND SURGICAL REPORTER.

*Abstracts* of the most valuable articles appearing in other publications are made and their sources acknowledged.

*Formulæ* of tried value, and *Therapeutic Hints* from all proper sources, are regularly published, and the *Periscope* discovers miscellaneous items of interest and value not included in other departments.

A word with regard to our advertisers. Nothing is admitted to the advertising columns without keen scrutiny, and we are confident that our readers will find our advertisers in every way satisfactory and responsible. The policy of the REPORTER confines our advertisers to the advertising pages. Space in the reading columns is never sold, and reading notices are never given to individual advertisers. This, however, does not debar a discussion of any article which is deemed of sufficient interest to the profession, save in so far as such discussion would discriminate in favor of some individual advertiser.

The dilemma presents but two horns. All of our advertising patrons must be treated alike. Either the REPORTER must be conducted in the interests of the pro-

fession—a journal, with advertising however useful, incidental to medicine; or it must allow itself to be conducted by a variety of people, representing different interests, with medicine incidental to business.

The first has always been the policy of the REPORTER in common with all other first-class medical journals and one we do not propose to vary, as both our subscribers and our advertisers approve of it.

We commend our advertisers to the profession as desirable to deal with and as parties not needing the questionable recommendation of constant mention in the reading columns of the journal.

## ABSTRACTS.

### A NOTE ON THE NATURE AND TREATMENT OF "INFLUENZA."

Mortimer Granville in *The Medical Press and Circular* says: Whether or not the malady miscalled "Influenza" be, as I believe it is, a Chinese marsh fever, there are certain characteristics of this disease which, with the indications obviously arising from them, have been unaccountably overlooked by clinical observers and ignored by practitioners. In view of the reappearance of the malady in our midst it may be worth while to point this out and to ask a reconsideration for the whole subject of pathology and treatment.

It was in 1848 that I first made the acquaintance of influenza, and in what would now be regarded as very adverse circumstances. I was engaged in the quasi-experimental study of the so-called system of "Homœopathy," which at that time almost fascinated the intellectual portion of London Society, and was the subject of thought and talk of every *coterie*. I happened to be in the region of densest fog, and it was not until some three years later that I succeeded in reaching daylight with the discovery that Hahnemann in his "*similia similibus curantur*" had either perpetrated an elaborate travesty of wit or become the victim of an extraordinary fallacy. However this may be, I have never regretted, indeed, I am daily thankful for, the close study of symptoms, states, and the direct and indirect action of drugs, dietary, and *conditioning*—what we now call "nursing"—on the organism in disease I was thus led to pursue. In respect to influenza, three facts which then came to my knowledge are of such *practical* value that I would not for any consideration be ignorant of them; and yet, so far as I know, they are not even mentioned in any text-book of medicine or in any special treatise on this disease. Briefly they are these: 1st. The temperature—we had no clinical thermometers in those days, but estimated bodily heat tolerably correctly by the hand—is a bogus one. It is not inflammatory, and a fatal mistake would be, and, as a matter of fact *is*, made by so treating it. 2nd. There is *always*—though in a large proportion of cases overlooked, lobular, or broncho-pneumonia, that is active congestion of the lining membrane of the b onchial tubes extending to theair-cells atrthe outset of the disease. Very often the area of dulness—from engorgement—is so limited that it is not perceived, and it may change from place to place, in the same lung, or disappear in one lung and make its appearance in another in less than two hours. Important, almost pathognomonic as the existence of this broncho-pneumonia is, it does not necessarily produce any special symptom drawing attention to the fact. This is why practitioners fail to observe it, and it explains the absurd description "Influenza complicated with pneumonia." Broncho-pneumonia is the very essence of the disease, and it would be far better to call it "epidemic lobular pneumonia," and thereby avoid a world of confusion and mischievous mistake. 3rd. The treatment must be tonic throughout, and the diet especially nutritious and stimulating *ab initio*.

These were the facts learned in 1848. The explanation has come with recent years and fuller knowledge.

The high temperature is bogus, because

it is simply the results of a sudden transference of normally hot or only slightly super-heated blood from the deep vessels to those immediately under the skin and in the mucous membranes. This is the direct effects of poison on the nerve centre, the poison of epidemic broncho-pneumonia acting specifically upon the vaso-motor centre. After the rush of the blood to the *surfaces*, external and internal, there is sometimes a rapid reversal of the state of matters and the blood falls in again upon the deeper vessels, and particularly those of the liver and kidney. When this occurs the temperature falls suddenly to a subnormal point. These are not, however, the worst cases. If the effects of the poison on the vaso-motor centre are sufficiently powerful to "stagger"—almost paralyse it—the result will be asthenic dilatation of branches of arteries supplying special lobules of the lung, with result of immediate hypostatic congestion. If this last long enough in any particular region a typical pneumonia my be fully developed; but it frequently happens that the particular nerve affected recovers and the muscular fibres of this artery act again, while another branch or filament supplying some other lot shows the paralyzing effect of the poison. The poison still acts on the centre, but its influence passes from branch to branch of the vaso-motor nerve. All this time it is possible that the blood state, as distinguished from the blood-vessel state, may be natural. The mean temperatures of the blood is, as we know, 39° C., or 31.2° Reau, or 102.2 F. (a very common temperature early in influenza). So that the mere transfer of naturally hot blood to the surfaces accounts for a great part of the temperature observed. If the action of the poison on the vaso-motor centre be prolonged nutrition is disturbed and a slight rise will rapidly bring the temperature to 104. or 105°. Indeed some physiologists place the mean of the blood heat at 40°C., which would give 104F. or 32°R. at the outset.

The point to note is that the great factor in the production of the high temperature in influenza is the bringing of normal blood to the surfaces *i. e.*, within reach of the clinical thermometer, and that this phenomenon is a result of "shock" to the vaso-motor centre, and needs to be treated by stimulants not by depressants. In such a case the coal-tar derivatives, antipyrine, etc., are simply murderous agents, and I do not hesitate to affirm that cases of influenza treated by these drugs are placed in jeopardy by a blunder in art, and that the mortality of the disease has been in great part the effect of the treatment. The depressant came into action at the moment of collapse, and rendered recovery impossible.

I believe the best treatment of influenza —or as I prefer to call it epidemic broncho-pneumonia—to be by camphor and iodine combined, as follows:—

℞ Camphoræ, ..... gr. lx:
Tincture iodi, (*a*) ..... m lx;

(*a*) To avoid the depressing potass iod. so strangely introdoced in the tinct. iodi of the "Brit. Pharm."

Mucilaginis acaciæ, ..... ℥iv;
Glycerini, ..... ℥vj;
Olei menthæ piperitæ, ..... m vj;
Syrupi zingiberis, ad ..... ℥ij.

Two teaspoonfuls being given every second or third hour until recovery happens, with clearing up of the lung congestion. Meanwhile—*during the stage commonly regarded as inflammatory*, be it observed —a highly nutritious diet of meat-juice or very strong beef-tea with a sufficient allowance of champagne or brady must be insisted upon. Rarely does the malady persist more than from three to five days, and when it subsides the patient is so little exhausted that the convalescence is extremely short. The chest should be daily, sometimes twice or three times in the twenty-four hours, searched for suddenly appearing or lingering patches of congested lung, and hot stupes of turpentine or mustard poultices applied if delay occur in the recovery of the arterial tone.

I do not urge this or any other particular mode of carrying out the indications, but I maintain that these are to make a vigorous attempt to arouse and support the action of the vaso-motor centre; and to avoid anything and everything caused by any chance depression. It is not an inflammatory disease we have to combat, but a poison which threatens to kill our patients by mere collapse, and the high temperature, the congestion, and the neuralgic pains are symptoms directly arising out of, and fully explained by the inhibitory effect of the poison upon the nerve center in the manner and with the results described.

## TYPHOID FEVER AND DRINKING WATER.

We have 50,000 deaths annually from typhoid fever, and we know how to prevent these deaths. Why do we not do it? It is estimated that the life of the average adult is worth to the State $1,000. If a young man of from twenty to twenty-five years of age loses his life, it will cost $1,000 to raise another up to the same age; and I am sure that any father who is engaged in the pleasurable occupation of raising a family of boys will deny that it can be done so cheaply. But on this estimate, this Government is losing 50,000 times $1,000 or $50,000,000 annually in death from typhoid fever. This is not all that typhoid fever is costing us. For every death from this disease, at least ten other people are sick with it. Five hundred thousand people who do not die are sick each year with typhoid fever. We will suppose that the average duration of the sickness is twenty-eight days, and all phycians will agree that this estimate is too low. The person who has typhoid fever is often unable to resume his vocation within a shorter time than three months. However, we will make our estimate on the supposition that the average time lost from work by a man sick with this disease amounts to 500,000 times twenty-eight days, or 14,000,000 days which is equivalent to more than 38,356 years. Supposing that the time of the individual is worth 50 cents per day when he is well, this represents an actual loss of $7,000,000 annually, and this should be doubled, because for every person sick the time of another person who acts as a nurse is demanded. The $14,000,000 added to the $50,000,000 which is lost by death makes a total sum of $64,000,000 or about $1.00 for every inhabitant, the annual tribute levied upon this Nation by the one disease, typhoid fever. This represents approximately the amount which we pay every year for the ignorance and carelessness which we exercise in allowing this preventable disease to prevail among us.

I have said that typhoid fever is a preventable disease, and that the large number of deaths from this disease is unnecessary. This is true, not only theoretically, but practical demonstrations are not wanting. Prior to 1859 the city of Munich, in Bavaria, was a veritable hotbed of typhoid fever. There were no sewers and no public water supply. Most of the houses were furnished with large brick or wooden flues which were built from the cellar up through the different floors. Into these the excretions from the body were dropped and accumulated in the cellars. Other waste material was deposited in cesspools, and garbage was thrown into back yards. The air in the houses was foul and offensive to the sense of smell. The drinking water was taken from shallow wells in the yards, and these often received the ooze from the cesspools and vaults. In 1859 the citizens were compelled to seal tightly the bottoms and sides of these receptacles of filth, and later, a system of sewerage was introduced, and later still a supply of wholesome drinking water was obtained. Notwithstanding the fact that portions of the city still remained unsewered at the time of the last report, the results have been most gratifying. From 1852 to 1859 the typhoid deaths per 1,000 in Munich averaged 24.2. This has been gradually decreased, until in 1884 it was 1.4 per 1,000. This shows what has been done in an old and crowded city, and Vienna has practically repeated the demonstrations made by Munich. The majority of cases of typhoid fever arise from a contaminated water. That a drinking water infected with the discharges from a person sick with typhoid fever may cause an epidemic of the disease, there can no longer be any doubt. The records of sanitary science abound in histories of such cases. Every physician of large experience with this disease can detail one or more instances in which the disease has been clearly traced to infected water and I will consider that this method of the dissemination of the disease is recognized by all. It probably is a safe estimate to say that bad drinking water causes not less than 40,000 deaths each year in this country.—*Prof. Victor C. Vaugh, M. D., in the New York Independent.*

## PROLONGED INTERMITTENT TREATMENT OF SYPHILIS.

Prof. E. Lang read a paper before the Medical College of Vienna in which he criticised the treatment of syphilis advocated by Prof. A. Fournier (Paris), who has now been induced, as the result of a long experience, gradually to increase the duration of the treatment from nine months, as recommended by him several years ago, to five or six years.

The author is of the opinion that the method devised by the distinguished French syphilographer is not in conformity with the natural evolution of syphilis. Syphilis being a curable affection at any stage of its development and even before the appearance of the secondary manifestations, it is evident that no single method of treatment will do in all cases. The therapeutical means employed must necessarily vary according to the necessities of each individual case.

In a recent publication (*The Medical Week*, 1893, Vol. I, p. 35), Prof. Fournier gives some statistics based on 1,703 cases of tertiary syphilis which, from the point of view of the duration of the treatment, may be classified as follows:

| | |
|---|---|
| No treatment | 217 cases. |
| Treated for less than one year | 1,162 " |
| " from one to two years | 265 " |
| " for more than two years, | 53 " |
| " for more than three years, | 6 " |

Prof. Fournier concludes, therefore, that out of 1,703 cases of tertiary syphilis, only 59 occurred after, and in spite of, conscientious treatment, while in the remaining 1,644 cases the accidents were due to the fact that the patients had only been very inperfectly treated, if at all.

Prof. Lang pointed out that supposing Prof. Fournier still believed that twelve months' treatment were sufficient to cure syphilis, he (Prof. Fournier) would be obliged to admit, in presence of the foregoing statistics, that tertiary manifestations occurred in 217 patients who had not been treated and in 324 (265+53+6) who had been submitted to appropriate treatment for the required period of time. The obvious conclusion would then be that, so far as the tertiary manifestations are concerned, prolonged treatment is worse than total absence of treatment.

To show that cerebral syphilis can be prevented by his method, Prof. Fournier quotes 100 cases of syphilis of the brain which can be tabulated as follows, according to the duration of the treatment:

| | |
|---|---|
| Prolonged and conscientious treatment | 5 cases. |
| Treatment of average but insufficient duration, | 6 " |
| " for from 7 to 18 months | 10 " |
| " for from 1 to 6 months | 70 " |
| No treatment | 4 " |
| Treated by iodide of potassium alone | 5 " |

This table shows, according to Prof. Fournier, that "only 5 out of 100 cases of cerebral syphilis had been submitted to conscientious treatment, while in the remaining 95 cases the treatment had been *nil* or only very imperfect or of short duration. From which it follows that cerebral syphilis is 19 times less frequent after conscientious treatment than in patients who have not been treated at all or only very imperfectly."

This statement is open to the same objection as the statistics already quoted, and Prof. Lang believes that the following conclusions may equally well be drawn from the facts brought forward by Prof. Fournier, showing how far the figures given by the eminent specialist are deceptive:

(1) Five patients out of 100 have taken nothing but iodide of potassium as against 95 who have either not been treated at all or have been submitted to some other method of treatment; from which it follows that cerebral syphilis is 19 times less frequent in patients who have been treated by iodide of potassium alone than in those who have taken mercury or nothing at all.

(2) In four cases out of 100 no treatment was applied, while in the remaining 96 mercury or iodide of potassium was administered; from which it follows that cerebral syphilis is 24 times less frequent in cases in which no treatment is employed than in those in which mercury or iodide of potassium is administered.

Indeed, Prof. Fournier himself admits that he has met with cases of recovery from syphilitic disease of the brain in which the patients had undergone a prolonged course of treatment, as well as with cases in which the patients remained free from specific manifestations of any kind, eight, twenty-four and even thirty-four years after a short period of treatment.

So far from exerting a favorable influence in cases of syphilis the method of prolonged treatment recommended by Prof. Fournier is apt, according to the author, to produce a deleterious effect on the patient's general health by giving rise to various alimentary troubles associated with insomnia and other nervous symptoms of a somewhat grave description, and favoring the occurrence of tertiary manifestations. For example, the statistics communicated by Prof. Fournier to the First International Congress of Dermatology in 1889, show that the liability to tertiary manifestations increased in his patients until the third year after infection, a fact which is in direct opposition to the experience of the advocates of the "opportunist" method who have never met with the same liability to tertiary accidents during the first three years after infection in the patients under their observation.

The statistics communicated by Prof. Fournier to the Congress were based on a series of 3,429 cases, in 1,085 of which the nervous system was the seat of syphilitic lesions, a very large proportion, even after deducting the 355 cases of tabes which are regarded by the distinguished French syphilographer as of syphilitic origin.

Lastly, Prof. Lang pointed out that Prof. Fournier has never reported a single case of reinfection in patients treated by his method, the occurrence of reinfection being a most conclusive proof that the patient had been completely cured of his first attack of syphilis. Another disadadvantage of the prolonged treatment consists in the fact that certain patients are very liable to relapses irrespectively of the method of treatment to which they are submitted; if such patients are already under the influence of mercury the administration of this remedy is not attended by the same success as it would be under other circumstances.

Dr. Finger spoke in favor of the prolonged treatment of syphilis. He maintained that so far as the liability to tertiary manifestations was concerned it was inaccurate to say that it was increased during the first few years after infection under the influence of the prolonged treatment.

Dr. Mauriac also communicated in the First International Congress of Dermatology some statistics on the same subject, from which it would appear that the tendency to tertiary accidents is greatest between the third and the sixth year, after which it gradually decreases. These facts were confirmed by the observations of Haslund and Leloir.

With reference to syphilitic diseases of the nervous system it should be borne in mind that this category comprises, according to Prof. Fournier's classification, such affections as locomotor ataxy, progressive general paralysis, the various amyotrophies, etc.; hence the large number of cases of this kind reported by this observer. As a matter of fact, Dr. Mauriac arrived at the same conclusions. It must be admitted that the prolonged internal administration of mercury is apt to give rise to various troubles, which can, however, be avoided by exhibiting the remedy in the form of external applications. Moreover, reinfection is not a conclusive proof that the individual had completely recovered from his first attack of syphilis, for there are a few cases on record of patients who had been reinfected while suffering from typical tertiary manifestations. The principal argument in favor of the prolonged treatment is the necessity of preventing the occurrence of tertiary accidents. It is generally recognized that the milder the secondary the greater the liability to tertiary manifestations; this is due to the fact that the treatment is seldom continued for any length of time when the disease assumes a mild type to begin with. Consequently some of the virus remains in the organism where it sets up various pathological processes at a subsequent date in the absence of appropriate treatment.

It is more rational, therefore, to combat the effects of the virus without interruption. The tissues being the seat of infective processes for three years after inoculation, the patient should be more or less under treatment during the same period of time. To prevent mercury from accumulating in the system, the administration should be suspended at intervals to permit of the elimination of the remedy. In concluding, the author said that he had employed the method of prolonged treatment for the last ten years with very satisfactory results.—*Medical Week.*

Cleanliness is next to godliness; but small boys should not go swimming on Sunday.

## ON THE CARE OF INFANTS AND YOUNG CHILDREN ACCORDING TO THE BIBLE AND TALMUD.

The following is an indication of the subject-matter of Dr. Finlayson's article in the *Medical Magazine*, October, 1893:—

The Talmud gives direction to the pregnant and the nursing woman as to the management of her health, particularly in the matter of diet, and it indicates the evils that may be expected to result from a violation of these rules.

The fœtus was believed to originate from three sources—the father, the mother and the Lord. To the first it owed the white portions, whence were derived the bones, nerves, whites of eyes, etc. The second contributed the red portions, from which were developed the skin, flesh, colored part of the eyes, etc. God gave the spirit, the intellectual faculties, and the power of movement.

The Talmud teaches that an angel takes charge of the embryo from its very beginning, and educates the fœtus "in all sciences, but especially in the study of the Mosaic and Rabbincal laws. At the moment when parturition begins however, the angel gives it a slap on the mouth, and all it has learned is forgotten."

An explanation is given of the origin of sex. If the male seed gets first into the womb at coitus, a female child is the result, and *vice versa*. Indications, too are furnished for the detemination of the sex before birth. Thus, "a woman who is pregnant with a male child ought to have a better complexion, and the quickening should occur earlier, and parturtion also ought to be easier and less painful. The last mentioned circumstance is especially insisted upon by the Talmudists."

Hermaphrodites were excluded from civil and religious rights, but operations were performed to remedy some malformations such as imperforate anus and hypospadias. Allusion is here made to the tradition that Moses and Job had congenital abscence of the prepuce.

The desire for male issue was strong among the Jews, and Rabbi Elazer knew how to take advantage of it. He says, in answer to the question, "What is a man to do in order to beget male children?" "Let him disperse his money among the poor in alms."

The expression "stool," "stools," or "birthstool," which occurs in Pharaoh's order to the Hebrew midwives, has given rise to much discussion, and question cannot be regarded as settled. It is possible that "upon the stools" of the authorized version ought to be rendered "on the wheels"—*i. e.*, before the potter's vessel comes off the wheels, the idea being (and this view is supported by the midwives' reply to Pharaoh) that Pharaoh intended that the babes should appear to have been still-born and not to have been killed.

The fact of the prolonged period of separation of a woman after a female birth as compared with a male birth (as enjoined in Leviticus) is familiar to all and must appear strange to modern obstetricians. There is no doubt, however, that in the times of the Talmud, the idea was generally prevalent that a labor which resulted in the birth of a female child was more severe than that which gave birth to a male. To account for this supposed fact, a writer in the Talmud says that the female fœtus turns around before birth, so as to present with the face anteriorly, while the male presents with the face posteriorly. Curiously enough, a pseudo-Hippocratic writer describes the period of lochial purification as being from twenty-five to forty-two days for a girl, and twenty to thirty for a boy. His explanation, however differs from that of the Talmud.

The subject of circumcision naturally receives much attention from the Hebrew writers, and in the Talmud also expression is given to the popular notion that "the child born at the term of nine months, or of seven months, is regarded as viable, but it is considered not viable if born at eight months."

The Talmud further gives rules for deciding the question when a child has been actually born. It indicates the circumstances under which an operation compromising the life of the child is justifiable and ordains the breathing in of air as the means to be used to resuscitate the apparently still-born.

The after-birth was sometimes treated with oil, and wrapped in wool or cotton, as a smypathetic measure calculated to warm and revive the new born infant.

The Hebrew writers inculcate the duty that devolves upon mothers of nursing their own children, but abundant reference

is made to other nurses and it is probable that wet nurses were sometimes hired.

"In three different cases, females ought to make coition unfruitful by using a tampon in the vagina—viz., a delicate girl still immature, a pregant woman, and a woman who is suckling. The first, so that, if she chances to conceive, she may not have to atone for parturition by her life; the next so that a second fœtus may not be formed, and press to death the one already in the womb; and the last, so that her babe may not be caused to pine away by the occurence of pregnancy."

"Nursing women do not menstruate because the blood is transformed into milk.'

The weaning of children is often referred to. A very instructive allusion occurs in 2 Macc. vii, 27:—"O my son, have pity on me that bare thee nine months in my womb, and gave the suck three years, and nourished thee, and brought thee up unto this age, and endured the troubles of education."

The prophet Isaiah speaks thus of the growing child:—"Butter and honey shall he eat when he knoweth to refuse evil and choose the good."

## INTRAVENOUS INJECTION OF SALINE SOLUTION IN SEVERE HEMORRHAGE.

Dr. P. Horricks read a paper on this subject before the Obstetrical Society of London. He pointed out that injections of various fluids had been recommended for centuries in cases of severe hemorrhage, but it was Dr. Wooldridge who first advocated the use of normal saline solution in place of blood, the injection of which he said was attended with great danger and was less efficacious. Following up Dr. Wooldridge's ideas in this subject he had published his first successful case in 1891. He referred to the following theories and facts which had led up to the practice of saline transfusion:—(1) Death from hemorrhage results from failure of the heart caused by distension due to the great and sudden fall in the blood pressure; (2) In death from hemorrhage sufficient fluid remains in the blood vessels to carry on life if it could be made to circulate; (3) Theoretically, half the volume of blood could do the same work if it were given double the velocity; (4) The blood pressure could be raised if as much fluid were transfused as there had been blood lost. Dr. Wooldridge performed an experiment with two dogs as nearly as possible alike in size, etc. Both were bled to death, *i. e.*, until they had ceased to breathe and were pulseless. One was left untouched and never showed signs of life again. The other was transfused, the water used being equal in amount to the quantity of blood removed. The dog immediately jumped up and recovered without any signs of ill-effect. Since September, 1891, this method had been largely used not only in hemorrhage but in collapse without hemorrhage, though personally he had had no experience of its employment in the later condition. He would be afraid that the overfilling of the vessels might determine death from over-distension of the heart when the reaction set in. He thought, however, that no case of loss of blood should be allowed to pass without an attempt being made to revive the patient by transfusion. In all the cases referred to later the patients were pulseless, but he pointed out that even if a patient were not actually pulseless he or she might nevertheless have lost enough blood to determine death. Death in such cases was attributed to shock, etc., though in reality it was due to loss of blood. He had never seen any harm follow transfusion except a little suppuration at the wound over the vein.

*Case* 1.—E. L., æt. 29, was the subject of an extra-uterine gestation of some five weeks' standing which had ruptured, determining severe internal hemorrhage. She was immediately operated upon, but the quantity of blood effused was so great that she appeared to be moribund, breathing having ceased and the pulse at the wrist being imperceptible. The case appeared hopeless, but transfusion was persevered with until some *six pints* of saline fluid had been infused. The pulse gradually returned, and she recovered without a bad symptom, except some suppuration along the drainage tube.

*Case* 2.—The patient, æt. 33, had her last period November, 1892. She had an attack of pain in the abdomen on Febru-

ary 13th, and again on the 16th, when she became blanched. The circumstances being unsuitable for operation in the house she was brought to Guy's Hospital where she was immediately operated upon. It proved to be an ectopic gestation, and after the operation the patient was carried back to bed pulseless and hot water containing ʒj to the pint, of salt was injected until five pints had been transfused. The pulse returned. The patient made a good recovery though her temperature went up, reaching 101° on the 4th, and 103.4° on the 8th day, with vomiting and diarrhœa."

*Case* 3.—E. S., æt. 28. Had seen nothing for two months, though usually regular. A fortnight before she had been seized with acute pain in the abdomen with vomiting, and she passed blood *per vaginam*. On October 26th, on getting out of bed she fainted and became very pale. Before the operation the patient became quite pulseless, and intravenous injection was commenced as soon as the pedicle was tied. Six pints of saline solution were injected, and she made a good recovery.

*Case* 4.—A. T., æt. 36, in the seventh month of her eleventh pregnancy. had severe hemorrhage. Podalic version was done, during which the patient became pulseless and saline injection was begun when the pulse once more became perceptible at the wrist. An hour later it became imperceptible, so more saline solution was transfused, but in spite of a further improvement the patient sank and died. Post-mortem, a large effusion of blood was found in the left broad ligament with a tear in the cervix extending into the broad ligament. There was no blood in the peritoneum.

*Case* 5.—J. M., æt. 44, was admitted to Guy's Hospital with hemorrhage, due to cancerous growth of the cervix. The growth was removed by means of the galvano-cautery, but owing to its becoming too heated, copious hemorrhage followed. The patient became very collapsed and the pulse was almost imperceptible at the wrist. Just over three pints of saline solution were injected. The patient recovered in spite of the fact that both broad ligaments had been cut into, and the base of the bladder damaged.

*Case* 6.—This was another case of ruptured tubal pregnancy, and copious hemorrhage followed the partial detachment of the placental mass. Much time was also lost looking for a sponge which was erroneously declared to be missing. The patient was very prostrate, and seemed at death's door. Six pints of saline solution were injected but the patient succumbed on the fourth day from suppurative peritonitis.

*Case* 7.—This case was that of a young married woman who soon after marriage developed tubal gestation. Operative assistance was refused for the moment, but subsequently he received a telegram that the patient was being brought to the hospital. She, expired however as she was placed on the operating table. Brandy was injected subcutaneously, artificial respiration was tried, and then his assistant commenced intravenous injection, but with absolutely no result. After a few pints had been injected he opened the abdomen and removed the specimen of ruptured tubal gestation, which he showed. This case, he pointed out, showed the danger of delay, and also demonstrated the fact that the heart and vessels did not long retain their power of carrying on the circulation if once stopped. He suggested that the proceedure offered a better chance of success when the bleeding vessels could be secured before transfusion was begun.

Dr. Herbert Spencer reproached the author with not having referred to his (Dr. Spencer's) observations on this point, his case, published in April, 1888, being the first in which the transfusion of normal saline solution was resorted to. He agreed that a trial ought to be made of this method in every case in which death from hemorrhage was threatened, but he urged that there should be greater accuracy in the proportion of salt used. He asked what physiological authority the author relied upon to prove his assertion that pure water might be used with impunity. By using a jug instead of a funnel the necessity for skilled assistance was dispensed with. The injection of very hot or very cold water might be followed by syncope, and some danger also attended too hasty an injection. In some cases, where the jug had been held too high, he had noticed recurrent pulsation in the veins, pointing to over-distension of the heart. He did not think that six pints was the outside limit of the injection, and in case of necessity he would not hesitate to employ more.—*The Medical Press.*

# CURRENT LITERATURE REVIEWED.

IN CHARGE OF ELLISTON J. MORRIS, M. D.

THE ANNALS OF GYNECOLOGY AND PÆDIATRY

for December. Dr. Frank W. Talley contributes a paper on

**Irrigation of the Non-puerperal Uterus.**

The instrument used by the author for the operation consists of a small canula, slightly bent at its uterine end to facilitate introduction, perforated at the end and sides, allowing the escape of the irrigating fluid in every direction, and provided with two pieces of wire soldered to its side, so that a space may be preserved between the canula and uterine wall, permitting the return flow of the fluid, and providing for the washing of the mucous membrane of the uterine canal throughout its course. The instrument has been made of such size as will just pass through a No. 15 French catheter scale. For convenience in office practice the author uses a speculum having the lower valve guttered and provided with a funnel on its distal end to which a rubber tube may be attached leading into a slop-jar placed at the foot of the table. The fluid used in the irrigation consists of a solution of one drachm of bicarbonate of soda, and thirty grains of carbolic acid to the quart of water at 110° F. From two to four quarts of such solution are used. The author advises that the cervix be mopped with a solution of carbolic acid 1:40 in order that no septic matter be carried into the uterus. The conditions which the author believes particularly applicable to the treatment are endometritis, metritis and subinvolution. He states that there is no danger of uterine colic if all the solution is allowed to drain away, and the uterus permitted to empty itself before the canula is withdrawn.

**Pelvic Congestion**

is discussed by Dr. Almon Clarke. The author believes that pelvic congestion is accountable in a great measure for the persistent nausea of pregnancy. Post partum hemorrhage he also attributes to the same cause and instead of the use of ergot recommends morphia and the tampon. Afterpains he also regards as the result of engorgement of the uterine vessels. The cause of the congestion he thinks in the majority of instances is constipation and the accumulation of feces in the large intestine and wherever pelvic congestion exists fecal accumulation should be looked for. If not found the case should be treated as if it were a known fact, and the treatment will often prove its existence. The treatment therefore should be directed to the relief of the accumulation of feces and should consist in clearing the whole length of the colon and keeping it clear, and afterwards promoting absorption and strengthening the weakened blood vessels by massage, electricity and such other local and general treatment as may be indicated.

Dr. Charles P. Noble presents the

**Report of Two Years' Work in Abdominal Surgery at the Kensington Hospital for Women, Philadelphia.**

Ninety-nine celiotomies have been performed with five deaths, none of which were due to infection on the part of the operator. The importance of early operation in pelvic troubles is urged by the author. In regard to the matter of the use of drainage, the author says that the only evil which he can attribute to drainage in his hands is that it prevents a perfect apposition of the abdominal wound and, therefore, he believes it is a predisposition to hernia. He drains all septic cases and all cases which he believes to be septic and all cases in which he expects much leakage after the operation. Gauze drainage he thinks is of value in certain cases. In incomplete operations and when there are extensive raw and vascular surfaces, he thinks it a most useful addition to the surgeon's armamentarium, but these conditions are seldom met with. It is to be used wherever the surgeon wishes to favor the formation of adhesions, which fact shows that its usefulness is limited, because, as a rule, adhesions are not to be desired. The author advocates the Edebohls method of suturing the abdominal wound by means of a row of buried sutures. Appended to the paper is a table of the operations performed.

Dr. Joseph Price presents the "Report of a Group of Interesting Cases of Abdominal Surgery." He reports the removal of an ovarian tumor from a lady aged 75 years. He dwells especially on the advantages of drainage in proper cases, the dangers and disadvantages of the use of opium in any form and the necessity of a previous surgical training in those who would undertake abominal surgery.

Dr. M. A. Poncet contributes an account of the final illness and death of Dr. Emil Blanc from a very acute septicemia of puerperal origin, through infection of the finger. The infection was received during the removal of the debris of the placenta from one of his patients, who was suffering from puerperal inflammation.

Dr. Thadeus A. Reamy reports the "Removal of Fibro-myomata with the Pregnant Uterus, Eleven Weeks Gestation, by Baer's Method. Recovery."

In the Department of Pædiatry is the report of a clinical lecture by Dr. H. Augustus Wilson on "The Mechanics of the Human Foot and Cases Illustrating Lost Mechanical Functions and their Restoration."

THE PACIFIC MEDICAL JOURNAL

for December. Dr. Harry M. Sherman describes a

**Splint Opener for Plaster-of-Paris Splints**

and other simple devices. In the saw for cutting the splint the back of the saw blade

is ground down to a knife edge for about an inch back from the point. Ten teeth to the inch have been found to make the best saw. The handle is put on a higher level than the blade by means of two elbows. The opener consists of two blades and handles joined so that when the blades handles are approximated, the blades are separated. The blades, when in contact, will just fit in the cut made by the saw and are held from slipping on the plaster by little serrations.

As regards the most convenient places for sawing the splints: on the upper arm the cut should be along the external surface, and if the splint is a spica of the arm and trunk, a second cut must be made through the trunk portion under the arm of the opposite side; on the arm and forearm the cut should be along the posterior aspect of the arm, over the tip of the elbow, and along the ulnar border of the forearm; on the forearm and hand it should be along the radial border of the forearm and hand and thumb, and the outer side of the forefinger.

In splints of the lower extremity, a spica of thigh and pelvis should be cut down the inner aspect of the thigh, and the pelvic portion over the ilium of the opposite side; on the thigh and leg the splint should be cut down its outer aspect; all splints that take in the foot should be cut down their posterior aspect and then along the sole of the foot.

The author also describes an aluminium chin collar and fork for use in supporting the head in cases of disease of the cervical vertebræ, and a night shoe for cases of talipes.

In the treatment of hip-joint disease by traction in bed, or in the treatment of cases after resection of the hip, or in any case where there is a tendency to rotation outwards or inwards at the hip, the foot-holder described in the paper is useful. It is merely a sole of wood fastened by its heel at right angles, to the middle of a slat of wood about ten inches long. The sole is strapped to the foot by webbing, somewhat as the old-fashioned skates were strapped on, and the slat lying on the bed prevents any rotation of the limb. A peg projecting from the toe of the wooden sole is to hold the bed clothes up from the foot.

The fastening of webbing and plaster and buckles *et id omne genus*, is a tedious process by needle and thread, and the eyelets ordinarily used weaken the material by cutting threads. The simplest way is by steel wire staples fastened by the hand-staple press, such as can be bought at any large stationer's tore, and are intended for fastening manucripts and pamphlets. These are easily adusted, hold firmly as long as they are needed and then are removed with little difficulty.

Dr. S. R. Mather reports "A Fatal Mistake" made by a French surgeon where the small intestine was found firmly sewed up in the wound made during an abdominal section. Symptoms of strangulation ensued soon after the operation but the surgeon had gone from the city and did not return in reponse to a telegram still the patient was moribund. She died duriug an operation for relief of the strangulation.

Dr. W. F. Southard concludes his paper on "The Modern Eye" and Dr. Gustav Dresel discusses the subject of "Ophthalmoplegia," reporting an interesting case.

---

THE NEW YORK JOURNAL GYNECOLOGY AND OBSTETRICS,

for December. Dr. William M. Polk contributes a paper on

**Hysterectomy (Supra-public) for Salpingitis and Ovaritis.**

He does not accept the proposal in whole, because by so doing, all idea of conservative surgery in dealing with the appendages is necessarily abandoned. He believes however that the uterus which is deprived of its appendages is not only useless to the individual but is a source of positive evil, and that the dangers of the operation are insufficient to forbid its application in the usual case of salpingitis. He says to those who repudiate conservative operations upon the appendages that complete work demands the removal of the uterus along with the appendages; and to those who accept conservative operations upon the appendages that when these organs are sacrificed the principles of conservatism to not apply to the uterus which should then be removed. He is of the opinion that the Trendelenberg position is a necessity in performing the operation and advocates the complete operation by means of ligatures instead of the nœud.

Dr. Marcus Rosenwasser discusses

**The Uterine Sound Its Use and Abuse.**

He describes the intrument, its indications and use as well as the counterindications and abuse. He lays down the following laws in regard to the instrument:

1. Let none use the sound who have not the necessary experience in bimanual palpation to make an approximate diagnosis in pelvic disease.
2. Strict asepsis of hands, instrument and field of examination are enjoined.
3. A thorough familiarity with the technique is essential.
4. Use the sound only for necessary information concerning the inside of the uterus not otherwise obtainable; or to induce early abortion; or to assist in replacing a movable uterus in exceptional cases.
5. Don't use the sound when irritation or inflammation already present would be increased; or when it would be the carrier of disease products or germs; or when its use would be likely to cause injury to agglutinated organs; or lastly, when the information gained would be inessential.

Dr. T. J. McGillicudy reports two cases of "Acute Puerperal Inversion of the uterus." One case died twenty-four hours after the accident, the other recovered. He is of the opinion that many cases of partial inversion or indentation at the fundus occur which rectify themselves, but which under favoring circumstances would have become cases of complete inversion.

The remaining papers in this issue are: "Subinvolution of the Uterus, and its Treatment by Electricity," by Dr. Charles G. Cannady; and a sketch of the life of Dr. Charles Jewett.

# PERISCOPE.

IN CHARGE OF WILLIAM H. BRICKER, M. D., B. SC.

## THERAPEUTICS.

### Chloroform as a Hæmostatic.

As a general hæmostatic for controlling of external bleedings, arterial, venous, or capillary, chloroform is most valuable. Applied on a dossil of lint or cotton wool to the bleeding surface, it promptly stays the blood, acts as a direct stimulant to the patient, and leaves no blood crust to fall off and recommence the bleeding. It is peculiarly suitable for all abdominal operations, as it has no tendency to excite inflammation either in the part to which it is applied or to any of the surrounding tissues.

As an antiseptic application it is more powerful than bichloride of mercury solution The addition of gum resins has been suggested, but they would detract from the value of the application instead of increasing it, for the reason which will occur to any person familiar with the use of solutions of gum resins.—*Medical Press.*

## MEDICINE.

### Congenital Absence of Right Kidney and Suprarenal Capsule.

The following case may be worthy recording: A man, aged fifty-one, was admitted into the asylum suffering from melancholia. He was a fairly well developed man but rather poorly nourished. The skin of his face and body was of a dusky brown color, the pigmentation being deeper in the regions of the axillæ, penis and scrotum. The heart's action was weak, and he had a small, feeble pulse. He complained of a feeling of nausea and frequent vomiting and retching. A tentative diagnosis of probable Addison's disease was made, and he was placed under special observation. The patient committed suicide by strangulation on August 17th. At the *post-mortem* examination the ordinary signs of strangulation were found; but the point of interest was that there was an entire absence of the right kidney and suprarenal capsule. On dissection, no trace of the missing organ could be found, nor was there any vestige of a renal or suprarenal branch of the aorta or vena cava on that side. The right ureter also was entirely absent, and on opening the bladder only the left ureteral apeture could be found. The left kidney was quile healthy but of large size, weighing 9½ oz.—Ernest W. James, M. R. C. S., in *British Medical Jour.*

### Some Observations respecting the Pathology and Pathological Anatomy of Nodular Cystitis.

Dr. Samuel Alexander, states that in certain cases of prolonged cystitis there have been observed, in addition to the usual changes due to chronic inflammation, a number of small nodules in the mucus membrane of the bladder resembling the enlarged solitary lymph-follicles of the intestine. These nodules in the bladder vary in size from a small pin-head elevation to that of a large pea. Their number and situation likewise vary in different cases. Simular nodules have been observed in the posterior urethra, in the ureters, and in the renal pelves, but the study of these lymphoid formations in the urinary tract has excited very little interest, and it is still an open question whether the nodules observed in inflammatory conditions represent a normal part of the mucous membrane of the urinary tract, or to be regarded as new pathological formations. After a long and painstaking investigation, Professor Alexander has arrived at the following conclusions in regard to this condition:

1. That the lymphoid nodules which occur in certain cystites represent a part of the normal mucous membrane of the bladder, and that the same is true in regard to nodular inflammations of the renal pelves, the ureters, and the posterior urethra.

2. That when there are a great number of lymphoid foci in the normal mucous membrane, infection of the bladder, if prolonged, is likely to assume a peculiar type, due to the enlargement of these foci into prominent and very vascular nodules, and that these cystites should be regarded as a special clinical variety, to which the name nodular cystitis should be given.

3. That in cases of tubercular infection of the bladder, in which there are numerous lymphoid foci present in the normal bladder, these become enlarged, and as a result of the special infection undergo degenerative changes which are characteristic of tuberculosis.

4. That the lymphoid foci in the normal mucous membrane vary greatly in size and number, that prominent lymphoids nodules may occur in a bladder apparently normal, and without previous inflammation. This, however, is very exceptional, and it cannot be positively asserted whether the enlargement of the nodules in these cases is a normal or pathological condition.—*Jour. of Cutan. and Genito-Urinary Dis.*

### Post-Mortem Idrosis.

A writer in the *International Medical Magazine* records the following curious phenomenon in a case of death from angina pectoris. "The face of the corps seemed to be bathed in perspiration, the moisture reproducing itself after being wiped off, in spite of the presence of rigor mortis and other unmistakable evidences of death. This most extraordinary phenomenon was witnessed by several local physicians who also viewed the body. The funeral was on that account delayed several hours until decomposition had fully set in."

### The Chemistry of Fatigue.

According to Lagrange, the general effects following fatigue are due in part to the chemical changes which take place in the muscles as the result of physical exertion, and in part to the changes induced in the various organs in consequence of their increased functional activity of which exertion is the cause. The chemicial changes which are produced in a muscle in activity consists in the formation of diverse abnormal chemical products, the residue, in fact, of excessive combustion, which always accompanies muscular contraction. There is present in a muscle, which is over fatigued, lactic acid, creatinine, uric acid, and these products gradually find their way into the blood, and so become generally disseminated. In the course of some hours they are eliminated by the urine as chemical analysis shows. While, however, these abnormal products are circulating in the blood they cause symptoms of a more or less toxic nature, such as a feeling of malaise, general lassitude, prostration, and sometimes even a rise of temperature.—*Med. Press and Circular.*

---

### Functional Diseases of the Alimentary Canal Accompanying Climatic or Temperature Changes—Etiology, Pathology and Clinical History.

Dr. F. W. Shaw in concluding his paper offers the following conclusions:

First as to etiology:

1. Any cause at any time of the year which creates in the intestines a condition of catarrh.
2. Fatigue or sudden chilling of the body.
3. High temperature and humidity.
4. Micro-organisms contained in air, water or food.
5. Any intestinal irritation or absorption of poisonous ptomaines.
6. Infection externally from decomposition of stools.
7. Active specific bacilli.
8. Age and individual powers of resistance.

Pathology:

1. Simple congestion of intestinal mucous surfaces.
2. Inflammation of stomach and intestinal mucous surfaces with loss of epithelium, and in severe cases loss of mucous and submucous tissue with intestinal infiltration.
3. Ulceration with loss of substance.
4. Infiltration of solitary and mesenteric glands.
5. Formation of membranous coatings to intestine.
6. Grave constitutional symptoms with no marked pathological intestinal changes.

Clinical history:

1. Simple gastric or intestinal dyspepsia with nausea and vomiting with no constitutional symptoms.
2. Enteritis, gastro-enteritis, entero colitis and colitis with marked local and grave constitutional symptoms, approaching in the latter case those of collapse.
3. Sudden death within a few hours of attack, with no intestinal signs of pathological changes.
4. Diarrhœas in all degrees of intensity, frequency, color, consistency and composition.
5. Vomiting, consisting either of mucous, undigested food or other stomach or intestinal materials, bile, blood or serum mixed with intestinal contents.
6. Specific action of certain pathological germs upon starches and sugars, resulting in an acid fermentation, and lastly, a similar action of other germs upon albuminoids, resulting in an alkaline fermentation.—*Brooklyn Med. Journal.*

---

### The Condition of the Urine in Relation to Anæthesia.

Porter, of New York, writes in the July number of the *Post-Graduate* quite a long paper upon the subject, and concludes:

1. That either and chloroform act upon the same principles, but with results developed by slightly different methods.
2. That both are capable of producing death at the time of the anæsthesia; cholorform more frequently than ether.
3. That ether causes as many, if not more, deaths than chloroform, but the fatal issue is delayed until the patient has recovered from the operating-table.
4. That by a careful study of the density of the urine and its causes we are in possession of exact information by which we can determine the nutritive condition of the system and are forewarned as to the possible outcome of the anæsthesia. It also enables us to judge which anæsthetic is best adapted to the individual case in question.
5. We are taught that neither ether nor chlorosorm should be administered until the glandular organs, in their necessarily damaged state, are put in the best possible condition to endure this extra strain. When this is a general rule many cases that now prove fatal will be saved.
6. It teaches that every public institution should have paid a physician who is competent to examine the urine and determine through it the status of the physiological economy before giving the anæsthetic. It should also be the duty of this same physician to administer the anæsthetic, for he alone knows best which anæsthetic to select with a given condition of the system, and is also better able to guide the patient safely through the anæsthesia than one who knows nothing of the constitution of the patient except from a second part.
7. While it is clear that death in some instances is directly due to the primary effects of the ether and chloroform, and in others to the secondary effects, it should not deter us from using them, but stimulate us to be more throughly master of their actions upon the system and to guard against their ill effects. When all this is accomplished, chloroform will probably hold the first place as an anæsthetic.

**Hernia of the Appendix—A Report of Forty-one Cases.**

Dr. Briege, of Breslau, has collected a series of 41 cases, 20 inguinal, 15 femoral, and 16 variety not stated. In 26 cases operation was performed; 16 cases were entirely cured, two were cured, but had a fistulous opening remaining, five died, and in three the result is not stated. From a study of these cases, Dr. Briege comes to the following conclusions:

(1) Hernia of appendix vermiformis is more frequent than is generally accepted.

(2) It is impossible to diagnose with certainty a hernia of the appendix. Where there are present the symptoms of an incarcerated hernia in the right inguinal or femoral region, one should think of the possibility also of a hernia of the appendix.

(3) A hernia of the appendix may produce more or less severe complications, inasmuch as the appendix is so frequently the seat of pathological process.

(4) This form of hernia demands early operative interference, because of the threatened complications which may arise from the appendix.

(5) This operation must, almost without exception, consist of resection of the appendix. The appendix must not be returned unless absolutely normal.—*Archiv. fur Klin. Chir., Ann. Surg.*

**Variola, Varioloid, and Varicella.**

Biedert agrees with the conclusions of McCollom (*Boston Med. and Surg. Journ.*):

1. That varicella is often accompanied by considerable disturbance of the general economy.

2. That varicella is not necessarily a disease of childhood only, at least not of very early childhood. To which conclusions Biedert would add:

3. Varicella is sometimes to be distinguished only with difficulty from mild cases of varioloid or modified small pox in those who have been vaccinated. Under some circumstances it cannot be distinguished with certainty.

4. This has reference to the diagnosis only, and of course not to the real identity of the diseases.

Of variola he draws the following conclusions:

1. Up to the stage of eruption, variola is either not contagious or less so than later. Light varioloid is much less so than severe or very severe variola.

2. Many unvaccinated individuals show a lessened susceptibility; by others the susceptibility is so great that even one or two years after vaccination they are liable to the disease.

3. In the majority of individuals vaccination protects for seven years; in a larger or smaller number considerably longer.

4. Protection begins about eight days after successful vaccination. Vaccination after infection has already taken place does not protect; yet it is possible that the course of the disease is favorably modified, if the vaccination has been done at least seven days before the eruption.

5. Vaccination laws are insufficient in so far as they permit many children to remain for a long time unvaccinated, and thereby become possible sources of an epidemic, as was the case in the present epidemic.

6. The more persons unprotected by vaccination and by revaccination, the greater is the danger in a community of an outbreak and of the spreading of an epidemic.

7. Isolation and disinfection are the more unsuccessful, in combating the disease, the more unvaccinated and improperly vaccinated persons there are in a neighborhood. An immediate vaccination of all such is necessary.

8. Energetic ventilation and the exposure of persons who come in contact with the patients to fresh air diminish the danger of contagion. Steam disinfection of the effects removes the danger from that source. Disinfection by sulphur alone may be sufficient.

9. In regard to treatment, these studies add nothing to what is already known.—*Archives of Pediatrics*, 1893 *Jahr. f. Kinderk. Leipzig*, 1892.

## SURGERY.

**The Value of Stretching the Sphincter Ani in Chloroform Collapse.**

In the long sad lists of deaths, says Dr. Alexander Duke (*Lancet*, London,) from chloroform in which the various means adopted for resuscitation (unfortunately ineffectual) are enumerated, I observe no mention of one of the most valuable, in my opinion, viz., *dilatation of the sphincter ani.*

This proceeding has been, I understand, in use in America for some time past, and is highly spoken of by Dr. Daily, in the *New York Medical Times*, Feburary, 1893, as effective in cases of morphine poisoning.

I had lately an opportunity of putting to the test this plan of treatment in the case of a patient almost moribund after chloroform administration. The usual means having failed to obtain any response, I introduced my thumb into anus, and forcibly drew the sphincter towards coccyx. This had the immediate effect of rousing the patient sufficiently to gasp and cry out, and when repeated later on (as she showed signs of relapsing into the former condition), she so far recovered as to protest in a marked way against its repetition.

Dr Daily's plan is to use a bivalve rectal speculum, and by its expansion to stretch the sphincter. As the speculum may not be always at hand, I think the finger (or thumb being stronger) will be found to effect the desired result.

Of course one case does not prove much, but by observation of its immediate effect in stimulating the respiratory functions, as stated in this paper, lead me to think it a most valuable and harmless proceeding.

The sphincter ani being the last portion of the body to give up its sensibility, the converse must be equally true, hence the importance, to my mind, of adopting this plan when the patient after an anæsthetic shows signs of collapse.

I trust that trial will be made of this American doctor's valuable suggestion, as I am convinced its importance is not known, and may be the means of saving life when the usual treatment has failed.

### Resections of the Kidney.

Kummel (*Arch. fur Klin. Chir.*) publishes an interesting article on the subject of "Resections of the Kidney," in which, after referring to some experimental reasearches with regard to resections of the kidney in animals, he describes his own experience of three such operations in human subjects—noting similar operations already performed by Czerny in 1889, and by Waitz in the same year.

Of the writer's three patients, the first was a woman, aged forty-one, from whose right kidney he removed a stone of the size of a walnut. Finding a portion of the kidney practically destroyed by multiple abscesses, he removed that part of the organ. The wound made in the kidneys was only partially sutured—that part of it left open was sewed to the skin—and packed with iodoform gauze. The wounds healed completely, though slowly, and the patient made an excellent recovery.

The second case was a male, aged fifty-four. The chief symptom was pain and tenderness in the region of the right kidney, and hæmaturia. An incision was made parallel with the costal arch. On exposing the kidney there was seen at its upper end a yellowish area about the size of a walnut. This, together with a wedge-shaped section of the kidney, was excised. Sutures failed to control the hemorrhage. The kidney wound was thereupon fixed to the outer wound, and packed with gauze. The wound healed rapidly. The patient left the hospital at the end of three weeks, apparently well. Six weeks later he returned. A tumor of the bladder was then discovered. This was excised through a supra-pubic cystotomy. Rapid healing and recovery followed. The wound made in the bladder by the excision was sutured. Ten weeks after the last operation the patient died of pneumonia and empyema.

The third case was one of echinococcus of the kidney, in a woman of thirty-four. In this case the kidney was reached by a similar incision to that practiced in the two preceding cases. The kidney was greatly enlarged. Numerous echinococcus cysts were found, and freely incised. The cysts were then excised, together with portions of the kidney adjacent, by wedge-shaped incisions. The sutures failed to control the hemorrhage, as in the second case; and the kidney was, as in that instance, fixed to the outer wound and packed with iodoform gauze. About one-half the kidney was removed, the pelvis not being injured. This patient made a good recovery.—*Bost. Med. and Surg. Jour.*

---

Milton reports the "Extraction by Laparotomy from the Human Bladder of the Largest Stone ever recorded as successfuly removed."

This stone weighed thirty-four and one-half ounces. The patient was an Egyptian, aged sixty. A mass extending to the umbilicus could be felt, and a sound passed into the bladder came at once upon a stone. An abdominal incision was carried from the umbilicus to the pubes, exposing the anterior surface of the bladder. An attempt was made to strip the peritoneum from the ant terior face of the bladder; but it failed. Thereupon the peritoneum was incised freely. The bladder was next incised, from its summit to its neck anteriorly—its peritoneal covering being, of course, divided. After making two lateral wounds in the course of the first bladder incision, the stone could be delivered by upward pressure exerted by two fingers in the rectum. The bladder wound was closed, except for a small opening at its lower part, with silkworm-gut sutures; the peritoneum with catgut, and the outer wound, except at its lower angle, with silver wire. There was no peritoneal reaction afterward; and the patient recovered from the operation, but died about two months later. The autopsy showed advanced disease of both kidneys. The largest diameter of the stone was six inches.

This case is especially interesting in view of the recent advocacy from various quarters, of opening the bladder through its serous surface as well as below, in order to get more room to work in, in certain difficult cases. —*London Lancet.*

---

Dittel has recently reported a case of total extirpation of the prostate, with recovery, in a man of thirty-two, who had been suffering from severe hæmaturia. A suprapubic cystotomy showed the source of the bleeding to be from a tumor (afterwards shown to be a fibroma) springing from the prostate. The growth was thought to be too large to allow of satisfactory removal through the suprapubic wound, and it was reached from below by an incision from the coccyx to the anus, separating the rectum from its attachments and then exposing the prostrate by an oval incision. The urethra and bladder were not opened in this operation. Through this opening the prostate was wholly removed. The bladder was drained through the urethra, and the wound packed with iodoform gauze. The patient made a perfectly satisfactory recovery.—*Bost. Med. and Surg. Jour.*

## ORIGINAL ARTICLES.

### SPASMODIC TORTICOLLIS AND ITS MEDICAL RELATIONS.

F. X. DERCUM, M. D., Philadelphia.*

Before a body of learned specialists, an elementary review of the subject of torticollis would obviously be out of place. Certain facts, however, owing to the paucity of our knowledge on the subject, demand repeated and careful consideration. Ordinary fixed wry-neck, is of some interest to the neurologist inasmuch as most of the cases owe their origin to some primary disease of the muscles, generally the sterno-mastoid. As a result either of congenital lack of development or of trauma received during birth, the sterno-mastoid of one side is shorter than its fellow, and at the same time is rigid and sclerosed. That, however, fixed wry-neck is not always to be ascribed to this cause is shown by cases reported in which the affection was due to a tonic spasm of one sterno-mastoid, the spasm in turn being due to, or associated with, some affection of the eyes. Wadsworth (Trans. *American Ophthamological Ass'n.*, 1889, p. 381), reports such a case under the title of "Spasmodic Torticollis Apparently Due to Faulty Position of the Eyes and Cured by Tenotomy." Landolt (*Bull. Med.*, 1890, IV., 573), records two cases, one associated with paresis of the left superior oblique and another associated with paralysis of the fourth pair of nerves. Inasmuch as both cases declined operation, the causal relation of the eye symptoms could not be determined. Of the three cases reported, two occurred in young children and one in a girl of seventeen. All had existed since early infancy. These cases are important as indicating a possible relation of cause and effect existing between torticollis and eye-symptoms in children. That, however, some of these cases are due neither to eye troubles, nor to trauma received in childbirth, nor to faulty position of the head in utero, but are really due to defective development, is made probable by the observation of Osler (*Archiv Pediatrics*, 1892, p. 81), who noted the association of congenital wry-neck, with marked facial asymmetry.

*Spasmodic Torticollis* is an exceedingly interesting affection, because of the numerous and varied character of the problems which it presents. We know little of the physiological action of the motor nerve cells, and of muscular tissue, while of the pathology of spasm we know still less. There is probably, further, some good reason why local spasms predominate in the regions of the face and neck, but all that we could say at present would simply be speculative.

Regarding spasmodic wry-neck, we must, it seems to me, admit the following propositions: First, spasmodic wry-neck, is not necessarily spinal accessory spasm. While it is true that the sterno-mastoid and trapezius are decidedly involved in the majority of cases, the spasm is frequently not limited to them, but involves other muscles. Further, cases are on record in which no spasm in the spinal

*Clinical Professor of Diseases of the Nervous System, Jefferson Medical College.

accessory distribution was present at all, and in which, notwithstanding, rotatory spasmodic movements of the head occurred. Again, muscles other than the rotators of the neck may also be involved. Secondly, the constantly recurring rotation of the head is at times the outcome of purely local conditions, and in that sense is a local spasm; at other times, though more rarely, it is the outcome of the action of physiologically associated centers in the upper cervical cord and medulla, or, more rarely still, of the morbid action of a motor centre in the cortex, and in this sense resembles a volitional movement. Both of these propositions seem to me to be of great importance.

Regarding the first, it is frequently possible, by the careful study of the movements of the head, and of the action of the muscles of the neck to determine which of the muscles are actually at fault. However, this can often be done only approximately. The first point is, of course, to determine whether or not the spasm is limited to the spinal accessory supply. If not, what other muscles are involved. The importance of this study, in view of operative procedures, cannot be overestimated, and doubtless is one of the reasons why some cases of resection of the spinal accessory nerve are successful and why others fail.

Having carefully studied the movements and the muscles involved, the next point that suggests itself is to determine whether the case presents physiological associations of different and distant muscle groups. This association is seen at times in the concomitant spasm of both trapezii, and of the anterior belly of the occipito-frontalis, or of the elevators of the upper lip. There is present at times, also, an associated movement of the arm on the affected side. If this movement be in extension and pronation, it is probably a physiological association. Though of great importance, it is not always possible to differentiate between a purely local spasm and a movement indicative of some perversion of the normal physiological action. If such a differentiation be possible it is of the utmost value in suggesting to us the position of the lesion, if any. From what we know of facial spasm, we have a right to infer that the lesion may be situated either in the cortex, lower nerve center, or in the nerve trunk. It is probable that the larger number of cases, with which we have to deal, are cases in which either the grey matter of the upper portion of the cervical cord and medulla is involved, or in which the nerve trunks of the spinal accessory, or of the cervical plexus are at fault. Certainly if the cortex were more frequently affected, we should expect, as Gowers points out, associated movements of the eyes These are practically never observed. It is true, however, that other associated movements, especially movements of the arm and forearm are very suggestive of cortical disease. Pressure points, so frequent in facial spasm, are, as is well known, rare in torticollis, nor do we often have painful points over the spinal accessory or other nerves. Such a painful point was present in a case for a time under my observation, and was situated over the spinal accessory nerve. The subsequent history of the case, however, the nerve being excised, proved that the case was not one of purely accessory spasm.

Regarding the various medical measures for treating these cases, it is hardly necessary that I should go into detail. All present are familiar with the utility of such drugs as gelsemium, conium and morphia—and also their failure to cure—at least, in the vast majority of cases. It is hardly necessary that I should dwell upon the various other agents at our disposal—massage, electricity, and rest in bed—as they give only amelioration and fail to cure. It is to the surgeon that we turn, sooner or later, with the hope of securing for our patient decided, if not absolute relief.

Those who follow me this evening will, of course, have a great deal to say about the various surgical procedures that have been instituted. Certain facts, however, present themselves for mutual consideration. First and foremost of these is section, or rather ex-section, of a portion of the spinal accessory nerve. This expedient yields in a large number of cases marked benefit, and in some instances it is followed by a complete disappearance of the spasm. In three of my own cases, however, it gave comparatively slight relief, the reason being, doubtless, that the spasm was more or less generalized, other muscles being involved. One of these cases I had the opportunity of following up, and later, at

my suggestion, Dr. Keen operated upon her, resecting the posterior divisions of the first three cervical nerves. The operation had originally been suggested by Dr. Wier Mitchell. This expedient was followed by a very decided relief, though at last accounts the spasm had to some extent returned.

We can readily understand why if the spasm be very much generalized—if a physiological movement be represented by it—that the number of muscles involved may be very great. Thus, in addition to the trapezius and sterno-mastoid, some, or all, of the following muscles may take part: the splenius, the rectus posticus major, the rectus posticus minor, the trachlo-mastoid, the complexuses, the obliquus capitus superior, the obliquus capitus inferior, the semi-spinalis, the semi-spinalis dorsi and the multifidus spinæ. This array of muscles shows the utter hopelessness of securing absolute or permanent relief in some cases by any operation on the peripheral nerve trunks. However, such operations should always be attempted provided the case be not clearly proven to be of cortical origin.

It is both interesting and gratifying to learn in this connection that Dr. Keen's operation has been successfully repeated by Dr. C. A. Powers (N. Y. *Med. Jour.*, 1892, page 253). The patient was one in which there was very little involvement of the spinal accessory supply. Dr. Powers adopted the expedient of Dr. Keen, and the result was a complete cure. Mr. Noble Smith (Spasmodic Wry-Neck, London, 1891), has also performed the operation with a successful result. The recurrence of rotatory spasm after such extensive resection of nerve trunks as was practiced on the case reported by Dr. Keen, seems to point to the cortical origin of the disease. The propriety of a cortical operation in such a case naturally suggests itself and deserves serious consideration. The centre for the rotation of the head being situated, approximately at least, in the posterior portions of the first and second frontal convolutions just in advance of the arm centre, it would be, surgically, very accessible and could probably be electrically determined at the time of operation. Inasmuch, however, as the centre for rotation of the head and neck appears to be closely associated with that for conjugate deviation of the eyes, such an operation should only be contemplated as a dernier resort.

Regarding other surgical procedures, such as stretching of the spinal accessory nerve, or tenotomy of the sterno-mastoid muscle,—they merely deserve mention. They are little more than makeshift expedients. However, an operation devised by Collier (*Lancet*, 1890, I, page 1354), deserves special mention. Collier, it will be remembered, tried the effect of a ligature upon the spinal accessory nerve. The ligature was a silver wire and was twisted with sufficient force to lightly compress the nerve fibres. Strange to say, the expedient was entirely successful, the spasm ceasing absolutely. The same expedient was, however, repeated by Drs. Mills and Deaver with failure as the result.

---

Dr. Thomas H. Manley, surgeon of the Harlem Hospital, New York, read a very interesting paper before the section of railway surgery at the Pan-American Medical congress on "Torsion and the homologous ligation of divided arteries." After treating the subject in his thorough, scientific and practical manner, the doctor makes the following conclusions:

Whether homologous ligation or obturation of arteries, the former by a living tissue and the latter by torsion of the vessel, possess any enduring value, experimental work and clinical observation alone will decide. Torsion is a very ancient expedient, which suffices for the diminutive and superficial vessels, but for those very deeply lodged or those of very large caliber, it has not been very generally trusted until recent times. Since the attention of the profession has been called to the subject by Professor John B. Murdock, who has revived it on a large scale, and has shown that with the perfected technique, with modern dressings and the elimination of suppuration from fresh wounds, its application has a very large field. As for homologous ligation, I am firmly convinced that with the onward march of progress in the near future, the question of perfected hemostasis will be definitely settled. Time and opportunity permitting, it will be my aim to continue my experimental work, and test to the fullest this species of automatic obturation in the human subject, and report final results later.--*Buffalo M. and S. Jour.*

## TREATMENT OF VENEREAL BUBO.

W. FRANK GLENN, M. D.,* NASHVILLE, TENN.

In considering the treatment of venereal bubo we must give careful consideration to the exact condition of the glands when the case is presented, also to the cause of the bubo. By venereal bubo we understand any inflammation or enlargement of the lymphatics of the groin, dependent either upon gonorrhœa, chancroid or syphilis. We will therefore consider the treatment in the following order: First, sympathetic inflammation of the inguinal glands from gonorrhœa or chancroid. Second, virulent or specific bubo. Third, the indurated bubo.

In treating the usual form of bubo from gonorrhœa or chancroid, namely, sympathetic inflammation of the inguinal glands (I use the word "sympathetic" for want of a better one to express the meaning), all steps should be taken to subdue the inflammatory process. First, by relieving the cause, viz, gonorrhœa or chancroid. Second, by such direct application to the glands as will tend to lesson the inflammatory process. First, then, I should advise absolute quietude, rest in the recumbent posture, with the constant application of ice to the inflammed gland. Also an injection, with a hypodermic syringe, of a one per cent. solution of benzoate of mercury, which seldom has to be repeated. If necessary, it may be injected again five or or six days later. If circumstances are such that the patient cannot be kept still, I should use the benzoate of mercury, advising the patient to apply ice with the ice-bag as often as possible. Sixteen drops of the one per cent. solution should be injected well into the substance of the gland, and a compress bandage should be applied and renewed twice every twenty-four hours. Welander, of Stockholm, claims ninety-one per cent. of cures of all buboes which had not reached the stage of suppuration, with this treatment. Letnick, of Odessa, out of one hundred and forty cases, claims complete resolution in one hundred and twenty. In the remaining twenty suppuration had begun before treatment was commenced, and he was compelled to incise the tumor. He proceeded as follows: Having made antiseptic the inguinal region, sixteen drops of one per cent solution of benzoate of mercury was injected into the swollen glands. Then a compress bandage, consisting of antiseptic cotton and a linen bandage was applied. The patient was required to observe the most perfect quietude during the entire treatment. I deem it unnecessary to even mention the many other methods that have been resorted to in venereal bubo to avert suppuration, since statistics show results from this plan which far excell all others.

If a bubo has not reached the point of suppuration when a patient presents himself, every effort should be made to prevent it, but if we fail after six days it is useless to try longer and we should encourage suppuration and bring it on as quickly as possible. When suppuration has taken place, and we have a soft fluctuating tumor, the gland should be incised, making an opening sufficiently large to allow the ready and easy emptying of its contents. The cavity then should be thoroughly washed out with hot sterilized water, using a small syringe for the purpose. Then inject a one or two per cent. solution of nitrate of silver and apply a compress bandage. Afterwards the cavity should be cleansed twice daily with a hot boric acid, or bichloride of mercury, solution, or with fresh peroxide of hydrogen, and iodoform, iodol, aristol or europhen thoroughly applied. While it would be better to keep the patient absolutely quiet for a week or ten days, it is not a necessity. The majority of patients will not submit to it, but attend to their business without serious inconvenience.

Dr. A. Cavazzani, of Venice, recommends the following powder as a dressing after the incision of suppurating buboes.

℞ Iodoform.....Ivss.
Salicylic Acid
Subnit. Bism.....āā 5ij.
Pulv. Camph.....3ss.
M.

The advantages he claims for it are: 1st. It prevents shrinking of the edges of

* Professor of Venereal Diseases in the Nashville Medical College.

the wound, so frequent with iodoform, and which so greatly retards cicatrization. 2d. It rapidly deterges the wound and almost completely suppresses suppuration. 3d. Under its influence the inflamed and tumefied glands rapidly diminish in size, and granulations spring up in abundance, in consequence of which cicatrization is greatly hastened. In many cases where suppuration has been slow and the glands have been inflamed a long time, it is well to curette after the pus is evacuated, but this is not often necessary.

Pontan treats suppurating buboes by puncturing the tumor, allowing the contents to escape, then injecting a ten per cent. mixture of iodoform and vaseline. He claims cure in six to eight days.

Teaclke makes an incision about one-third of an inch in length, through which the contents escape. The cavity is filled to distension with tincture of iodine. The iodine is then pressed out and an antiseptic dressing applied, and over this is placed a large sponge, covering the entire inflamed area. In twenty-four hours this dressing is removed, and all fluid remaining in the sac pressed out and the dressing re-applied. While his treatment is painful, he claims rapid cures.

Wertheim advises puncture of the tumor with a large aspirating needle, through which most of the fluid is drawn, then a four per cent. solution (eight or ten drops) of muriate of ammonia is injected. As the fluid in the cavity accumulates it is again tapped and treated in the same manner.

Zeisse applies compresses wet in a solution of subacetate of lead, and keeps the patient confined to bed. As soon as pus is formed it is evacuated by means of a small puncture. When in spite of drawing of the pus there are marked symptoms of inflammation, the skin is laid freely open, the cavity curetted and packed.

In the treatment of bubo there is no doubt but it would be better to excise the gland as soon as it becomes inflamed and close the wound by suture, thereby getting union by first intention. But circumstances will not often admit of this, as the majority of patients refuse positively to submit to it. Where suppuration has set in, I do not believe that anything can be gained by excision over free incision, curetting the cavity if necessary and applying an antiseptic dressing.

In the treatment of the virulent bubo of chancroid, after free incision has been made, we must regard the cavity as a chancroid and treat it accordingly. Thoroughly cauterize the walls of the cavity with nitric acid and then apply iodoform and a compress bandage. Cleanse and redress the wound twice a day. It is first a suppurating bubo, but after it is incised and its contents emptied, it remains a chancroid.

Syphilitic indurations of the inguinal lymphatics need no local treatment whatever, as they seldom suppurate and gradually disappear under the influence of proper internal medication.

## GASTRO JEJUNOSOTOMY FOR MALIGNANT OBSTRUCTION OF THE PYLORUS; DEATH FROM ASTHENIA ON THE EIGHTH DAY.

JOHN B. ROBERTS, A. M., M. D.,* PHILADELPHIA.

A man, aged fifty-eight years, presented himself to me with the history of having had some pain in the abdomen and some digestive disturbances for nine or ten months. About four months previously to his consulting me he had noticed a small tumor at the umbilicus, which after a time became slightly ulcerated upon the surface. The tumor on examination was about an inch in diameter and seemed to involve the entire thickness of the abdominal wall; no attachment to deeper structures could be detected. The sallow complexion of the man and his general debility led me to believe that there must be some deeper growth. Examination of the chest revealed nothing especially abnormal, and nothing of importance was detected in the urine. The fact that violent vomiting occasionally occurred led to the suspicion that there might be malignant disease of the stomach and that the umbilical tumor which was evidently malignant was a secondary growth. Investigation of the

* Read before the Phila. Co. Med. Soc., November 22, 1893.

contents of the stomach, obtained by the use of the stomach-tube, showed an abscess of hydrochloric acid in the secretion. Examination by means of the gastrodiaphane gave no evidence of any growth involving the anterior part of the stomach, for the trans-illumination seemed perfect. The vomiting of large quantities of food led me, however, to make a diagnosis that there was some pyloric obstruction.

On October 7, 1893, the interior of the stomach was washed out thoroughly and the abdominal cavity opened for the purpose of exploration and the probable removal of the umbilical growth. Introductions of my finger revealed a tumor about the size of a woman's fist, involving the pylorus and the surrounding structures. As it was evident that the umbilical tumor was unimportant in comparison with the graver lesion of the stomach, I determined to leave the former untouched and make an anastomosis between the stomach and the jejunum. A loop of small intestine was fastened to the anterior wall of the stomach by two lines of continuous silk suture applied according to the method of Lembert. A row of interrupted sutures was then placed at the points where I desired the intestinal and gastric walls to come together in front of the proposed anastomosis. These sutures were left long and the stomach and intestine held apart so as to give me room to make an incision in both organs. At the ends of the proposed apposition, no sutures were applied as I believed I could protect the peritoneal cavity there with sponges until after the interrupted sutures in front were tied. The intestine was kept free from intestinal contents by two pieces of rubber drainage tube passed through the mesentery and loosely tied around the bowel, above and below the site of operation, so as to occlude its lumen.

The gut was then opened by an incision, two and a half inches long, made at a point opposite the mesentery and between the suture lines. The mucous coat was brought into contact with the serous coat of the bowel by whipping the edges of the intestinal wound with a continuous silk suture. The stomach was opened in the same way between the lines of suture, and its mucous and serous covering stitched together by a continuous silk suture whipping the edges. The interrupted sutures applied along the anterior portion of the apposition were then tied and reinforced with an outer continuous suture. Afterward stitches were applied at the ends of the space apposed so that there was no possibility of leakage between the approximated surfaces. The abdominal cavity was then washed with hot water, and the parietal wound brought together. A continuous catgut suture was used for the peritoneum and the skin was united with silk stitches. The umbilical tumor was allowed to remain.

The operation was a difficult one on account of the manner in which the stomach was made immovable by the size of the growth involving its pyloric end. The patient reacted well, though the shock was marked because of the length of time required by the operation. There was some vomiting for a few days, the vomited matter being sometimes dark in color and fecal in odor. At first, feeding by the rectum was employed and the stomach given entire rest. At the end of about three days small quantities of food were administered by the stomach, and dilute hydrochloric acid given to allay the tendency to vomiting. This seemed efficacious and he took a fair quantity of whiskey, peptonized milk, beef-tea, and beef-juice, and retained these articles well. He died, however, of asthenia on the eighth day. For several days before death no vomiting had occurred and food and stimulus were taken quite freely. Strychnine and quinine were administered in the effort to keep up his strength, the quinine being given by the rectum, the strychnine by the hypodermatic method and by the stomach.

An autopsy was made a few hours after death. The abdominal incision was united superficially throughout its entire length. There was no evidence of suppuration and no redness. When the skin was pulled apart with the fingers about a drachm of yellowish fluid was found between the peritoneum, which was united, and the skin; and under each end of one of the sutures was a little hollow about the size of a pea in the superficial fascia. This fluid looked like pus, but was apparently lymph which had filled the space not closely brought together by sutures. The haste with which the sutures were applied because of the patient's depression caused the muscular tissues to be drawn together

imperfectly. As has been said, the peritoneum was united by first intention; and there was no evidence of septic peritonitis in any part of the abdomen. The peritoneal cavity was free from fluid, and the seat of operation was in a perfectly aseptic condition, the jejunum and the stomach being well united. The great omentum was found adherent to the anterior wall of the belly in the left hypochondriac region in front of the normal omental attachment to the stomach. Behind the coil of jejunum which was attached to the stomach by the operation there was room to pass four fingers with ease. The stomach was not much dilated; the malignant growth occupied both anterior and posterior walls, nearly one-half the distance from the pylorus to the cardiac end.

The anastomosis had been made just beyond the diseased area in the anterior wall of the stomach. The jejenum was supposed at the time of operation to have been twisted by me so that the contents of the stomach would flow into the intestine in the direction of the fecal current. The specimen shows that this was not accomplished and that the bowel was not turned as I had supposed. The size of the growth, occupying the pyloric end of the stomach and involving contiguous structures, was about three inches in diameter and irregularly globular. Its size and the infiltration of surrounding tissues account for the difficulty found at the time of operation in bringing the stomach into the wound, although the wound was four inches in length. The omentum was adherent at one or two points along the suture line of the anastomosis on the intestine; for about four inches below the anastomosis and about eight inches above that point the jejunum was somewhat dilated. Some small malignant nodules were scattered throughout the liver, and one or two similar spots of disease were seen on the surface of the intestines. The lungs were not removed, but seemed normal except some pleural adhesions at the apex of each lung. The heart was small but was not opened. The jejunum had been united to the stomach about four inches from its upper end. The union was perfect and the amount of lymph uniting the stomach apparently small. The superficial sutures were visible, particularly at one spot where the bond of lymph had been separated a little by the traction made during the removal of the specimen. The omentum lay behind the coil of jejunum which had been brought up to be united with the stomach. The communication from the stomach into the jejunum was found patulous, but admitted only two fingers from the stomach into the jejunum. There was no evidence of unhealthy inflammation at any point of the operative area. The edges of the opening into the stomach where the suture was used to whip the edges were united, as were the edges similarly sutured in the intestinal wall. The intestine when laid open showed that the communication between it and the stomach was satisfactorily healed on the intestinal side as it had been on the gastric side. The intestine below the seat of opening presented a congested appearance of the mucous membrane. The pyloric orifice of the stomach was contracted and surrounded by malignant masses. It would just permit the passage of the tip of my little finger passed from the stomach into the intestine.

*The most important lesson in the case is the fact that a two and a half inch orifice between the stomach and jejunum had contracted in eight days so that it was only about one and a half inches long and would admit but two fingers.*

---

**What the Doctor Gave Him?**

It is not often that one hears a really new medical story, but the following has every appearance of freshness and originality:—Long ago, a man went to Dublin to order a coffin for Pat Connell. "Dear me," said the undertaker, "Is poor Pat dead?" "No, he's not dead yet," was the reply, "but he'll die to-night, for the doctor says he can't live till the morning, and he knows what he gave him." The above anecdote occurs in Mr. Le Fanu's recently-published book, "Seventy Years of Irish Life."

---

LUBRICANT FOR CATHETERS.—Castor oil is an excellent material for this purpose. It is non-irritating and tenacious. It should always be applied warm, and the bottle containing it should be frequently washed with alcohol. It can be used for silk and rubber catheters alike.—DR. J. M. KITCHEN.

## THE TREATMENT OF SPASMODIC TORTICOLLIS BY CONIUM.

WHARTON SINKLER, M. D., PHILADELPHIA.

The treatment of spasmodic torticollis is most unsatisfactory. The pathology of the affection is so obscure that rational treatment is all the more difficult of application. Dana, speaking of wry-neck, says: "In rare cases it is cured, in many others it can be ameliorated, but it generally reaches a certain stage, and then remains chronic." Drugs of all kinds have been recommended in the treatment of this affection, and splints and mechanical appliances are not only of no benefit, but usually aggravate the affection. From the fact that frequently the muscles principally involved are the sterno-mastoid and the trapezius, the affection has been supposed to be due to disease of the spinal accessory nerve, and the treatment has been directed to this nerve.

Counter-irritation, galvanism, and actual cautery applied as near as possible to the origin of the nerve, have been used, but with far from satisfactory results. Surgical measures, such as stretching this nerve, and the excision of a large portion of it, have been resorted to, but in only a small proportion of cases has relief followed the operation. It is, therefore, evident that the disease, except in rare cases, involves the deeper muscles of the neck, as well as the sterno-mastoid and trapezius.

Lezynski recommends the use of belladonna, given in increasing doses almost to the point of toxic influence, and keeps this up for four or five weeks. He has had marked success from this method, and Gray states that since he has followed Lezynski's plan, he has cured eight cases of spasmodic torticollis by the use of belladonna. I have used this remedy myself, but without success.

The best results which I have seen from drugs in this disease, have been from the use of conium. This drug was recommended by Harley many years ago, in the treatment of spasmodic affections, but it never has been used extensively. G. M. Hammond reports the successful treatment of a case of painless facial spasm by the use of this drug, and Rockwell, of New York, recommended it in the treatment of chorea. The text-books, however do not speak of it favorably. Hare, in his work on Therapeutics, remarks, "that conium holds an unimportant place in the drug list of to-day." I have found in my own experience, however, that it is decidedly useful in many forms of muscular spasm when not due to central causes.

From experiment, it has been found that conium causes paralysis of the motor nerves when given in physiological doses. There are drooping of the eyelids, staggering and inability to walk, showing its influence upon the muscular system. It is, therefore, reasonable to expect that in the treatment of muscular spasm, when peripheral in origin, that the remedy would prove useful.

Harley recommended the juice of fresh leaves, but this is difficult to obtain and the fluid extract is a reliable preparation. The dose in which it is recommended in the text-books is entirely too small to be efficacious. I usually begin with fifteen or twenty drops, three times a day, and frequently increase the dose to sixty drops. There are two fluid extracts in the market: one of the leaves, and the other of the seeds. I usually give the latter.

I have seen several cases of spasmodic torticollis which were relieved by this remedy, and two or three cases of painless spasm which were distinctly benefitted by it use, in one of which the spasm entirely ceased. I will relate two cases to illustrate the successful employment of conium in spasmodic wry-neck.

CASE 1. Mary C., aged 26, a shirt maker by occupation. Her general health has always been good, and there is no history of special interest in connection with her present trouble.

She applied for treatment at the Infirmary for Nervous Disease, December 12th, 1887. She stated that two weeks previously there began a sense of trembling in the neck, and a heavy feeling in her head. At the same time the head began turning continually to the left side. On examination the head is found to be rotated strongly to the left shoulder. It can be turned to the front but can be held there but a few moments, when it is again rotated to the left. If the head is

held by force in a straight position there are felt strong spasmodic contractions of the sterno-mastoid and the trapezius muscles. She cannot turn her head as far to the right as to the left. There is no pain or tenderness over the vertebræ, soreness in the sterno-mastoid muscle or sensitiveness over the points of emergence of the spinal accessory nerve.

A blister was applied over the point of origin of the spinal-accessory nerve, and galvanism was used quite faithfully for four months; cod liver oil was administered and the patient was advised rest. But little change took place during this time, except that there were two brief periods of improvement, once after the treatment had been changed to the iodide of potassium. At this time the sterno-mastoid and trapezius had become more rigid, and the head after being voluntarily rotated to the front would be drawn to the left within a few seconds by the spasm of the muscles.

The patient was now ordered the fluid extract of conium in ascending doses, beginning with five drops, three times a day, and the maximum dose reached was twenty drops three times a day. This treatment was pursued for twenty days, when the improvement was so great that the head could be held straight for several minutes. The conium was continued until the patient was well, and when seen a few months later, the patient said she was entirely relieved of her trouble. A year latter there was a slight return of the spasm for a few days, but this again yielded, in a short time, to conium.

Case II. Miss G. M., aged 44 years, was admitted to the Infirmary for Nervous Diseases August 28th, 1893. Family history unimportant. She had always been well until four years ago. In November, 1888, while at work she became dizzy and fell, remaining unconscious for a few moments. It was found afterwards that her shoulder had been dislocated by the fall. The dislocation was reduced by a physician within a short time, but there was partial loss of sensation in the arm, and this has continued ever since. The head was turned towards the left immediately after the fall. The left ear almost touched the shoulder, and the head was so much rotated that the chin reached the point of the shoulder. The head remained in this postion for two or three days, when it gradually came back to the normal condition.

After the first fall she had dizzy attacks every two or three weeks; she did not become unconscious, but for a few moments she could not see and would then fall. The head would assume the position above described after each attack, would remain turned to the left for a few days and then resume the proper position.

While the head was drawn to the left shoulder, she could place it in other positions with her hands, but it would immediately return to the position of rotation to the left from the spasm of the muscles. After a time the attacks of vertigo became as frequent as two in a week.

In February, 1893, she had a severe attack, in which she did not fall, but she saved herself by sitting down in a chair. She was not unconscious, and could walk, but became rigid for half an hour. The head was drawn down until it reached the left shoulder. After this attack she was in bed for six weeks, and during this time she states that the whole left side was somewhat contracted. She had no falling attack since February, 1893.

On admission, the patient was found to be a well nourished, muscular woman; digestion normal; heart and lungs healthy; and the urine free from disease.

There is no paralysis of motion and sensation is normal, except in the right arm and shoulder, where it is delayed and diminished to tactile and thermal sense. The knee jerks are normal on both sides. The elbow jerk is exaggerated on the right side, but normal on the left. When sitting up, the head is drawn to the left and rotated so that the chin is turned towards the shoulder. All the muscles which turn the head towards the left, seem to be involved, but especially the right sterno-mastoid and left trapezius. She can turn her head to a normal position but cannot hold it there for more than a few seconds, when it is again rotated violently to the left. When she is lying down, the head becomes almost straight, and the spasm of the muscles does not occur. There has been, at times, a sharp pain in the left side of the neck in the trapezius muscle, but it is now a dull and dragging sensation. The facial muscles have never been affected.

If the patient places her right hand on the side of her head, so as to rest the head upon it, the head will turn to an erect position. The patient was ordered rest in bed, with general massage, faradism to the neck muscles, and the fluid extract of conium, 20 drops, three times a day, to be increased.

On September 7th, that is nine days after the treatment had begun, the patient was taking thirty drops of the fluid extract of conium, three times a day, and it was noted that the head was decidedly better, that she could hold the head straighter, and that when sitting up the head did not so frequently rotate to the left side. On the 14th of September, the patient was still improving. She could hold her head perfectly straight, without support, for a few minutes. She has less of the dull feeling and dragging sensation in the left side of the neck. The improvement continued, and on the 5th of October, the patient was able to hold her head absolutely straight, without any pain whatever. She was discharged from the Hospital, October 16th, entirely relieved of the spasm of the neck muscles, and seemed to be in perfect health otherwise.

Some of the attacks from which this patient suffered were undoubtedly hysterical and it is probable that the spasm of the neck muscles was also of an hysterical origin. The trouble had lasted for over four years, and was not relieved until she was placed under treatment by the use of conium.

## THE HYGIENE OF THE EYE.*

F. C. HEATH, A. M., M. D., Indianapolis, Ind.

Next in importance to life itself is the faculty of vision. No man, be he Crœsus or Vanderbilt, would consider his fortune for a moment in comparison with his eyes. How, then, to preserve the eye in a healthy state becomes an interesting question not only to the doctor but to every seeing member of the human family. Preventive medicine has here a field of transcending importance.

It may be said in a general way, that the eye is much affected by the constitutional condition and, therefore, is concerned indirectly in all measures of general hygiene, but it is the special hygienic measures necessary to the preservation of sight that claim our attention in considering this subject.

No feature of face or form compares with the eye in beauty and expressiveness, and as seen in childhood, with lustre undimmed by age or accident and with conjunctiva uncolored by disease or drug, it is to the oculist what the finest of paintings is to the artist.

First in time as well as importance comes the eye of infancy. To produce an ideal child it is said that we should commence two hundred years before he is born—to get good eyes would require equal attention to antecedents. But taking things as we find them, what is our first duty? Immediately after birth the child's eyes should be wiped with a clean cloth (the lids being closed). In bathing the first time, keep the water of the bath from the eyes—then clean them with cloth and clean water, dropping in one drop of a two per cent. nitrate of silver solution. This simple course, if followed by all obstetricians, would reduce the cases of blindness at least ten per cent. This I believe to be the ideal method for lying-in hospitals and for all cases of suspicious vaginal discharge in the mothers. How far it can be employed as a routine in private practice, or what substitute should be used, may be left to the judgment and the conscience of each practitioner.

Attention to cleanliness, general hygiene, and protection from too strong light or other injurious influences, suffice until our babies have become school-children.

In Germany and in some parts of this country, the hygiene of the eyes of school-children has received considerable attention but, in general, far less than the importance of the subject demands. Pre-eminent among the dangers at this stage is the production or increase of myopia

* Read before the Miss. Val. Med. Ass., 1893.

or "near-sightedness." This may result from prolonged use of the eyes on near objects, especially under unfavorable conditions. It was found in Germany, that myopia increased from twenty per cent. in the lower grade schools to sixty per cent. in the higher. Of 1133 school children whose eyes were examined in New York, less than four per cent. were found near-sighted at seven years of age, but nearly twenty-seven per cent. at twenty years. The practical point in the investigation was the discovery of the unfavorable conditions and their removal as far as possible.

Bad air and excessive heat were found to affect the eye muscles by enfeebling the system, and to indirectly increase myopia by tending to congest the eyes. A still greater factor in this direction is working in an improper position—with the head bent over a low desk, for example. The failure to regulate the height of desks according to the size of the pupils is about on a par with that method of distributing army clothing condemned by Dickens on the ground that "the tall soldiers got the short pantaloons and the short soldiers got the long ones." If desks are too low or of improper slope, or if seats are uncomfortable, the children are likely to lean forward, resulting in the double harm of congesting the blood-vessels and bringing the eyes too near to their work.

Perhaps the most important consideration, here, is the direction and amount of light. Cohn, who examined the eyes of over ten thousand school children in Germany, found 1.4 per cent. of pupils in *village* schools near sighted, and 11.4 per cent. in the *city* schools similarly afflicted, the difference in the proportion being attributed, principally, to the fact that the city schools were darkened by the height of surrounding buildings, while the village schools stood by themselves and obtained light in abundance from all sides. Defective light works injury by causing pupils to bring their work nearer, to make up for the deficiency. Too strong light, or light shining directly in the eyes, irritates the retina and conjunctiva, and also causes too close approach to the desk in bending to avoid the glare. The light should come preferably from the left side.

The kind and duration of work are the other factors worthy of special mention in the hygiene of the eyes of school-children. Small and indistinct print acts much like defective light. Greek and German text are especially trying. Writing with pale ink should not be allowed. Written examinations should not be too frequent. It will be admitted that written work, from its tendency to exactness, is a desirable educationable feature, but it should be employed far less than at present, when it is, undoubtedly, injuring the health and eyes of thousands of pupils and of teachers as well. The hours of study, too, are much too long, and intermissions are too short and too infrequent. Intervals of rest greatly relieve the eyes. If all students were to cultivate the habit of looking up from their books frequently to think over what they have been reading, it would be a source of great mental improvement as well as affording the eyes much-needed rest.

The removal of the above unfavorable conditions as far as possible, according to Von Hippel, has reduced myopia in Germany at least six per cent. In the face of these facts, is it not high time that we were doing something to arrest this growing evil in our own country? The responsibility rests largely with physicians as leaders of society and conservators of public health and welfare. Concerted action under our leadership should accomplish as much here as has been accomplished by the labors of our professional brothers in Germany.

Our school-children graduate and enter different lines of business, each perhaps with its especial dangers to the eye. Stone cutters, machinists, and those in exposed vocations, are liable to various accidents, especially from foreign bodies in the eye. Hence they require some form of protective glasses. These may be of glass, circular in shape, but if we wish to make them unbreakable, they should be of mica or wire gauze; these are, however, open to the objections that they obscure the light to some extent, and, if in the form of goggles, retain the moisture of the eye and hence may increase the irritation. To those whose work requires facing strong lights like the electric arc light, the best protection is in the smoked glasses. These should not be too dark, and should be worn only when absolutely necessary, lest they render the eye more sensitive to light than before, besides causing eye-strain from efforts to see through them.

The habitual use of these glasses from slight and insufficient causes is getting to be a very common mistake, indeed, it might well be added to the list of humanity's self-imposed ills as the "smoked-glass habit." These remarks are, of course, not intended to preclude the use of protectives when needed by actual disease or marked photophobia. They may, then, furnish great relief and even prove curative by affording rest and freedom from irritation. Blue glasses exclude heat-rays and lessen color rays, but give less protection than smoked and are less comfortable; other colors are far more objectionable. Shades, veils and curtains have their uses, also to be governed by the principles already laid down plus such common sense as the special occasion may demand.

In cases of severe disease and after operations, dark rooms may be an occasional necessity, but their bad influence on the minds and bodies of patients being appreciated, they should be used only when unavoidable, and then for but a short time.

Rest should be considered as one of the most important factors in treating diseased or strained eyes; rest of eyes, body and mind. Avoidance of wind, dust and smoke, or protection from their evil effects, must not be neglected.

Personal habits enter into the question of causation of eye disease, and their regulation becomes, therefore, a part of the preventive or hygienic treatment. Sexual excesses undoubtedly contribute to the production of muscular asthenopia and hysterical amblyopia and photophobia, besides affecting the conjunctiva indirectly through their influence on nasal catarrh. Tobacco and alcohol have their well-recognized amblyopias. Lack of bathing the eyes properly may result in conjunctival trouble. Use of water, both cold and hot, may have a place in the hygienic treatment of diseased eyes. Employ, as a rule, that which is the more grateful to the patient: cold usually for conjunctival diseases and injuries; hot for iritic and deeper troubles, avoiding anything like a poultice. Indeed, there should be a limit to cold applications lest the nutrition of the cornea become enfeebled, while that delicate tissue requires still greater care in the use of hot applications (seldom exceeding one hour at a time) from fear of maceration and consequent ulceration. Diet is important chiefly through its effects upon indigestion and general health, which frequently have much to do with the condition of the eye.

A few words as to abuse of eyes may not be amiss. The first offence in this line is reading with a poor light—requiring the cilliary muscle to do extra work to sharpen the vision. This applies to dim light, twilight, sitting too far from the light, etc.

The second offence is error of posture—stooping or lying down congests the eye, besides requiring unnatural work of the eye muscles.

Reading on trains is our third offence, the motion causing such frequent changes of focus and position as to tax the muscle of accommodation as well as the muscles of fixation, so to speak.

Reading without needed glasses or with badly fitting ones is our last, but not least, offence. Aside from the various well-known reflex effects of eye strain, the danger to the eye itself is not to be slighted. Eye strain is certainly a factor in producing disease of almost every part of the eye, its most serious effects being choroiditis, glaucoma and cataract.

Old age is the time of retribution for eye sinners—it calls for little in a special hygienic way beyond the occasional stimulating washes and the careful husbanding of what sight remains.

Fortunately the surgeon's skill can give nearly all sufferers from cataract a greater triumph over their troubles than is afforded any other sufferers whatever, yet it is only after quite a period of darkness in waiting the ripening of the cataract.

In this brief space, exhaustive treatment of the subject is out of the question, but our object has been accomplished if these hints lead to greater attention to an important field which has been sadly neglected.

---

A PHYSICIAN who got rid of some of his steel instruments and bought others made of aluminum says that he is sorry that he changed. The aluminum probes, sounds, tongue depressers, and that sort of thing do not oxidize, to be sure, but he finds that they are deficient in elasticity, and stay bent after pressure. He declares, moreover, that he likes to feel as if he had a hold on something when he uses an instrument, and aluminum is so light that it makes him feel as if he could put no trust in it.

# INFLUENZA AND ITS TREATMENT.

CHARLES B. WILLIAMS, A.B., M.D.,* PHILADELPHIA.

Influenza (syn. Epidemic Catarrhal Fever, Contagious Catarrh; French, *La Grippe*) is essentially an epidemic disease, running a specific and definite course and characterized by a catarrhal inflammation of the respiratory organs and sometimes of the digestive. There is pyrexia and a great deal of constitutional disturbance, with marked debility and depression of spirits.

EPIDEMICS.—The first epidemic of influenza that has been recorded in any medical record, occurred in 1510. But there can be no doubt that Aristotle and Galen saw epidemics similar to those which occurred in 1510 and those which at irregular intervals have occurred in our own times. Among the chief epidemics of influenza are those of 1762, 1782, 1787, 1803, 1833, 1837, 1847.

Watson, in his "Annals of Philadelphia," states that Noah Webster in his work on "Pestilence" says: "The city was again visited in 1747, by bilious plague" preceded by influenza. Watson further states that in August and September, 1807, the influenza prevailed in Philadelphia. Then we have the epidemics of the last few years, occurring since 1889, with which we are all more or less familiar.

CAUSES.—The Italians, in the 17th century, ascribed it to the *influence* of the stars, hence the term "Influenza" (Ital., *Influence*), by which the disease is now known. The more probable and more generally accepted theory is that influenza is due to some minute organizm of a specific nature, conveyed by the atmosphere and distributed over wide areas. This organism, when introduced into the bodies of those affected, increases and multiplies indefinitely, and hence we have another source of infection in the breath, etc. Anyone having carefully observed the course of the present epidemic would not venture to question the contagiousness of influenza.

SYMPTOMS:—The period of incubation may last from a few hours to as many days, or may extend to two or three weeks. The disease usually develops suddenly with rigor or chills followed by fever, the temperature ranging between 101° and 103° F. The pulse, at first frequent and full, soon becomes soft, weak and slow. At the same time the patient complains of severe aching and shooting pains in the back, limbs, chest, neck and eyes. Sore throat is a marked early symptom of the disease. Then follow hoarseness, coryza, deafness, dizziness, and sometimes nausea and vomiting.

The local symptoms vary in individual cases, but as a rule they begin in the nose and conjuntivæ and extend downward. There is an abundant watery discharge from the mucous membrane, accompanied by sneezing, with impairment of taste and smell. The mouth, tongue and fauces are sore. The inflammation extends further down, ending in either a laryngitis or a bronchitis, with possible complications of pulmonary congestion, capillary bronchitis or pneumonia.

Some persons are much less susceptible to the disease than others, while on the other hand, some appear to be altogether insusceptible. Influenza can hardly be termed a dangerous disease unless it ends in pneumonia. It is occasionally fatal to infants and to aged people. Then, as so many persons in every large community are "tottering on the brink of the grave," the influenza proves the immediate cause of the increase in the death rate during the prevalence of an epidemic.

The prognosis is especially grave in chronic pulmonary or cardiac disease. Hæmoptysis may not unfrequently occur in those predisposed to it. The writer has seen an example of this occurring in a patient residing in Montgomery County, Penna. The prognosis is also grave where there are evidences of weak circulation, or symptoms of adynamia, as in diabetes, Bright's disease, fatty heart, etc.

TREATMENT:—There is no specific for influenza, but it is possible, and indeed it is often highly important, to arrest the disease, or diminish its violence at its onset.

In the first place, *all* cases should be kept indoors, in a cool room, well ventilated, but free from draughts. If the case is seen early, Pulv. ipecac et opii gr. x., either alone or in combination with Pilocarpinæ hydrochlorat. gr. ¼–½,

* Ex-Resident Physician Pennsylvania Hospital, Assistant Surgeon to Methodist Episcopal Hospital.

taken at bedtime with a hot lemonade, will do a great deal towards diminishing the violence of the attack.

The above treatment will be found to ameliorate considerably the pains and cough, and the patient will feel relieved by morning. Quinine is a remedy usually well borne, and in combination with Strychnia, gives good results, especially where there is marked debility. The following formula will be found to be of excellent service in this stage.

℞ Quininæ sulphatis vel Cinchonidinæ salicylatis.....gr. xviij.
Strychninæ sulphatis.....gr. ss.
M. et div. in pil.....no. xij.
Dispense in capsul.
Sig. One pill t. i. d.

Should the patient still complain of pain or be restless at night, small doses of ext. Opii may be conveniently added to the above formula.

A prominent symptom of this year's epidemic has been a severe supra-orbital neuralgia, attended sometimes with shooting pains in the frontal sinuses. Indeed the neuralgia has shown a tendency to persist long after the active symptoms of the grippe have subsided. This pain may be due to pent-up nasal secretions or, on the other hand, it may be purely neuralgic. However, the following treatment will usually afford relief: Internally, large doses of the salicylates, preferably, Ammonia salicylatis gr. xv. q. q. h., and the instillation of a drop or two of a 1 per cent. solution of Cocaine hydrochlorate into the nostril of the affected side. If there is occlusion of the nares from pent-up nasal secretions causing pain in the frontal sinuses, then the occasional use of Dobel's solution with the atomizer, may be all that is necessary to relieve the patient.

One can readily see that the treatment of influenza resolves itself almost entirely into symptomatic treatment.

For the bronchitis that usually follows: In the early stages the following formula, advised by Dr. H. C. Wood, is valuable:

℞ Potassii citratis.....ʒss.
Succus limonis.....fʒiss
Syrup. ipecac.....fʒiij.
Glycerinae.....fʒss.
Aquae.....q. s. ad fʒij
M. Sig. fʒij, q. s. h.

Should there be extensive bronchitis and the secretions accumulate, and there are evidences of pulmonary congestion, then Antimonii et potassii tart. gr. ss., may be conveniently added to the above formula. Eucalyptol vel Terebene, m v. in capsul. q. q. h. will also act well in this complication.

Where expectoration has been established and is no longer tenacious, an expectorant mixture containing Ammonium chloride may be substituted for the above.

Alcohol in the form of brandy or whiskey, and best administered in egg-nogg or milk punch, is required where there is much debility and in old persons who need stimulus, from the start of the disease.

The diet must depend on the individual case. Should the case be a severe one, large quantities of concentrated liquid nourishment are required. Usually most patients, in the first few days of the disease, refuse nourishment in any form whatsoever. The writer has found that boiled milk seasoned with a little salt, will be taken and relished by these patients who could not be induced to take any other food.

During convalescence, tonics together with nourishing food and some mildly-stimulating beverage, as wine or beer, are required. Change of air is beneficial, but the patient must guard against taking cold and sustaining a relapse.

---

### On Tobacco Smoking.

Gounod loved his pipe dearly. In this connection the following words of his have an interesting bearing on tobacco smoking and its effects:

I admit sincerely the truth of Tolstoi's opinion in all that has to do with the intellectual faculties. I think that the habit of using tobacco produces a sluggishness of these faculties, that this sluggishness follows upon the habit, and by abuse may reach even to atrophy. I am not so sure that it could possibly result in the annihilation of Conscience, whose witness is too startling to undergo so easily an eclipse so disastrous. I say Conscience, be it noted; I do not say Will. Conscience is a Divine decree; Will is a human energy. The latter can be weakened by abuse of the organs; the former, however, seems to me quite beyond all effect of the sort, because it creates the responsibility without which man ceases to be amenable. I have smoked a great deal. I do not recall that it has ever modified the judgment of my conscience on the morality of my acts.—*Review of Reviews.*

## A CASE OF INCARCERATED HERNIA OF A DIVERTICULUM OF THE INTESTINE.

Dr. E. v. Laczkovich says diverticular herniæ of the intestine are rare, and still more rarely do we find an incarceration of the same. Mery in 1701 was the first to report such a case. Meckel's diverticulum, which can be regarded as the only true one, is formed by a partial opening left from the ductus vitello-intestinalis or the omphalo-mesaraicus, and is found along the ileum about 1 m. from the ileo-cæcal valve. Several other authors have described isolated cases (Walter, 4; Grendig, 1; Gravitz, 1;) in which a diverticulum was found at the jejunum but regarded as identical with Meckels.

In the case reported, a diverticulum of this description was found incarcerated in the right inguinal ring. The hernial sac contained nothing but the diverticulum. The constriction was located beneath the diverticulum, inclosing a portion of the intestinal wall. The case is interesting aside from its rarity, by the fact that the partially gangrenous intestine, was neither reduced nor resected, but following the advice of R. Graefe and Th. Rorsing, it was left outside of the abdominal cavity in its hernial sac, after having released the stricture and removed all constricting tissues.

This treatment was followed by good results, in spite of the presence of greyish spots in the prolapsed tissue and the opaque appearance of the peritoneum. The intestines, on the day following, showed such marked improvement in color and general appearance that reduction could be performed without fear.

The report is as follows:—J. S., age 56, was admitted on September 13, 1892, to the surgical department of the general hospital at Budapest. History was as follows:—On the 9th of September, while lifting a heavy piece of machinery, weighing 50 kg., he suddenly experienced great pain in the right inguinal region, followed by swelling. In spite of the increasing pain, he worked until the 11th, on which day he was unable to get up. After another attempt on the 12th, to continue his occupation, he found himself compelled to go home and go to bed. A physician was called, who diagnosed incarcerated hernia, which he attempted to reduce without success. Careful examination showed a swelling, the size of an egg, in the right inguinal region, painful upon pressure. The skin could be lifted and was of normal consistence. Abdomen slightly tympanitic; some inclination to vomiting; last movement September 9th; pulse frequent and compressible.

Incarceration having existed four days, no attempt was made at reduction of the tumor, but herniotomy was at once decided upon. After opening the hernial sac there was an escape of about one teaspoonful of reddish-brown, opaque, odorless fluid. The sac contained a prolongation of the bowel, about 3 cm. long, 1½ cm. wide; its upper portion was dark red and lustreless, with numerous greyish patches. After loosening the stricture and separating the fibrinous attachments formed in the ring, the intestine was drawn forward, which showed plainly the constricted portion, which was, however, not yet gangrenous. The suspicious appearance of the above-mentioned attachments induced the author to surround the intestine and pack the opening with iodoform gauze, leaving all within ready access. After the operation free movements of the bowel occurred. On the 14th of September he changed the dressings. The intestine, appearing normal, was replaced; drainage tube inserted; wound closed with sutures and dressed with iodoform gauze. Free bowel movements daily. The patient was discharged on the 27th inst., cured.

This case is similar to that of Graefe and Rorsing, and the result being equally as good, affords encouragement to adopt the treatment in such cases where gangrene is not complete.—*Centralb. f. Chirurg.* No, 36. —W.

* Translated for THE MEDICAL AND SURGICAL REPORTER by the translators M. B. Werner, M. D., and W. A. N. Dorland, M. D.

## THE PLASTIC FORMATION OF A SPHINCTER FOR THE LARGE INTESTINE.

In the year 1889, the author, Prof. R. Gersuny, Vienna, (*Centralb. f. Chir.*, No. 25,) described a new operation for the correction of incontinence of urine. The method consisted in dissecting from the adjacent parts, the urethra, which was then twisted on its long axis, presenting a corkscrew appearance, after which the urethral orifice was united to the surrounding tissue by sutures. This presented an elastic resistance to the contents of the bladder. The author reported at the same time, the history of a patient so operated upon, and also the persistent cure after a longer period. The only possible objection, if it could be called that, being that the patient required more time to empty her bladder than if she had a natural sphincter.

The success of this operation induced the author to carry out the same theory where extirpation of the lower portion of the rectum, including the anus, became necessary for the removal of carcinomatous degeneration. He presents with history, two cases upon which he performed this operation. He was enabled, after having extirpated the diseased tissue, to draw the bowel down to the integumentary incision, having previously twisted it on its long axis—as he had done with the urethra—and fix it to the skin with sutures.

Recovery was prompt. Union perfect in both cases. Both were enabled to retain even watery stools. Shortly before leaving the hospital, a digital examination was made in each case, which resulted in finding a circular, elastic constriction of the lumen of the bowel, 2 to 3 cm. above the external opening. The mechanism of this closure rests chiefly upon torsion, and its success upon the normal elasticity of the tissue. This is particularly essential if the cures are to be permanent.

A correspondence after discharge from the hospital, brought satisfactory answers, the one eleven weeks, the other sixteen days after having left the hospital.—*Centralb. f. Chirurg*, No. 26. —W.

## THE PROFESSIONAL HORIZON.

DAVID W. CHEEVER, A. B., M. D.

*Audi alteram partem.*

The master mariner in olden times scanned the horizon, watched the currents, estimated the tides, studied the winds to guide the good ship on her course. All these were variable and changeable; but the magnetic needle, the sun, moon, and stars were unvarying guides. So the modern steamship master may disregard the winds, surpass the tides, defy currents and storms; but yet he is always dependent on the compass, the quadrant, and his solar and stellar observations for his position, his progress, and his prospective voyage.

Thus, too, the older surgery, contending with obstacles and evading dangers, by its care and skill, although by devious routes, often landed its patient safe at last.

While modern methods, more rapid and direct, may lead straight on to recovery and to life, yet, although newer observations, newer science, newer instruments of precision, may modify and may advance modern surgery and medicine, the principles of the science and art remain the same as they were before; and, if disregarded, they lead to failures in practice, or at best to temporary success.

In scanning, like the old sailor, the professional horizon, may we not learn from the omens of storms or calms, where we have gone astray from the unerring guides of sound professional principles?

The unbalanced predominance of operative surgery has destroyed all natural and harmonious proportion between operations and surgery; and between surgery and medicine. Antisepsis has insured an immunity which over-emboldens the operator, and which substitutes the precipitate certainty of an incision for the well-con-

sidered conservatism of diagnosis and delay. No one can deny that anæsthesia first, and antisepsis next, have enormously increased the domain of operative surgery. No one can assert that much of this is not both useful and hopeful. And yet, in proportion to other surgery, operations should fill a second place. The rare has become the common, and the common has been pushed aside and neglected. Contusions, abscesses, fractures, varicosities, atheroma, are the every-day things we always see; and abdominal diseases have usurped undue attention, and displaced the common classes of surgical events.

Diseases of the joints, affections of the lymphatic glands, maladies of the bones, ulcers, the endless variety of affections of the rectum in modern sedentary life,—these, like the poor patient, we have always with us. Such cases filled the text-books, and supplied a large part of the surgeon's practice. But to-day, if the student or practitioner opens the pages of the present surgical text-books, he finds that genito-urinary surgery and that of the abdomen and the brain occupy one-third of the space. Pages are devoted to the multiple and fancy stitching of an intestine, and a paragraph suffices for piles; yet one hundred people have piles, and require treatment from the surgeon, to one who has intestinal obstruction. The new is interesting, the new is important; but it is overdone. Perspective is lost: the natural proportions of classes of cases obscured. Rare things are magnified; common things are overlooked.

There is also constant danger of confounding functional and temporary with organic and permanent conditions: of operating for a symptom, and finding a phantom tumor. Visceral surgery replaces therapeusis. Forlorn hopes are common operations. Exploratory incisions made for diagnosis may be often innocuous where no disease is found, but are very fatal where organic and incurable affections exist. It used to be said that it was fatal to explore a tumor, outside the body, unless you could take it out. It is equally dangerous and often fatal to explore a visceral tumor, in spite of antisepsis.

Is there not danger, also, that the ease of looking breed littleness of wit; that intuition, that sum of experience, may shrink and waste, when unused; that the balancing of chances, the estimating of probabilities, the struggle for a diagnosis, may be belittled in face of reputed certainties revealed by a cut, and thus delay sober judgment? Is not the therapeutic use of drugs also much unlearned by this fatal ease of operating? Obscure brain affections, nervous habits, apparently organic and incurable growths, sometimes yield to medicine, and escape the knife. We may not often thus succeed; but does not the fact that we do not try medication lead finally to a loss of knowledge as to the chances of a trial?

Specialties magnify regions, distort wider vision, focus the attention on a point and ignore a more important whole. A diathesis, a constitutional bent, often directs or influences the general progress of a disease. A symptom may be local, or general. If local, it is seen; if general, it may be easily overlooked. Habit may perpetuate an epileptic crisis in spite of the operative removal of the local cause of the aura. A vent boldly given to a subarachnoid hemorrhage may not prevent a fatal result due to the plugging of the nutrient vessels of the pia mater. Clots in the spinal canal may be absorbed, sometimes, with less hazard than by removing the laminæ and uncovering the spinal cord.

The treatment of the diseases of women has become almost purely operative. Attention to constitutional treatment is thus easily diverted.

The sexual maniac is spayed, often without lasting relief. Pelvic cellulitis and peritonitis not very rarely are lighted up by hasty interferences with the interior of the uterus.

Life is occasionally shortened by too early removal of innocent growths about the ovaries and uterus. So intensely has the attention been called to the right iliac fossa, that an appendicitis is suspected in every colic; incisions are sometimes made before walling off has occurred; an organ removed which was the seat of only temporary catarrhal obstruction, and the adhesions of an excision substituted for the adhesion of a transient inflammation.

Is any incision harmless? Certainly it is not. A scar is left; sensibility is increased. If in the abdomen, the binding power of the fasciæ is weakened. Hernia may result; or, at any rate, prevention may require an abdominal supporter to be worn ever afterwards. In gunshot wounds of the intestines a certain percentage of

cases may recover without operation. Extravasation may be prevented by the pouting of the mucous membrane through the perforation of the ball; and the latter may be discharged *per rectum*. Of course, the majority die. But so, unfortunately, do most of those operated on. The history of such cases is scanty, the pathology new, the results few. Let us by no means discourage research, experiment, or even operation; but let us make haste slowly.

In the charm of asepsis, in the ease of healing, in the painlessness of operations and of recoveries, we are apt to overlook that great factor, shock. The effect upon the nervous system of a disease, an injury, an operation, is hard to estimate. It often turns the scale against recovery. Especially about the neck; in the three great cavities of the body; in any operation on the extremities which approaches the centre, the results of prolonged and teasing operations are often fatal through profound and prolonged shock. It has been recently advanced that age makes little difference in the prognosis of an operation,—an opinion from which we absolutely differ. No one who has watched the old but has seen prolonged shock of the nervous system, and evidences of impaired mental activity, long subsequent to operations of even moderate severity.

The somewhat ungrateful task of advancing heretical opinions, in the preceding remarks, can be condoned only from our profound conviction that the operative *furor* of modern surgery is resulting in a serious detriment to the best qualities of sound diagnosis, sound pathology, and surgical therapeusis: to diagnosis, because we do not exhaust means of harmless research; to pathology, because we operate to know what is the matter, and not from proved pathological processes and results; to therapeusis, because we neglect much that can be accomplished by regimen, by rest, by sedatives, by alteratives and by time.

When we survey the medical horizon, we find equally great changes. That harmony of knowledge and character which made the general practitioner many-sided, but symmetrical—*Sapiens, teres, atque rotundus*" (Horace); that self-reliance which equalized extremes, balanced chances, judged impartially—have been sadly damaged by the fatal facility of the habit of consultations and by the narrowing spirit of specialism.

A great ignorance of the simpler products and processes of pharmacy has accompanied as great a lack of careful study in therapeusis. The medicine is now made to hand for the doctor by steam and chemistry; and the useful combinations of older drugs are swept aside.

Bred myself in an era of therapeutic nihilism, experience has failed to confirm my unbelief. On the contrary, long trial has convinced me that we can accomplish much with a few, well-selected, familiar and potent remedies.

If the surgeon and physician have changed, the lay public has changed faster. Credulity is undiminished. Modern witchcraft rivals the older kind. Therapeutic nihilism has become a system and a school of medicine. Practice has lost its stability. Formerly there was a family physician, whose patients retained him as a familiar and much-used fixture until he died. Now he shares a family with others; and he does not look on any person as his patient for life. This is a greater loss to the community than to the doctor. We regret, but we yield to these revolutions.

Meanwhile should we take a depressing view of our professional future? By no means; for never was surgical and medical science so bold, so advancing, so successful. Never was the young doctor so well educated as now. Never had he so large a clinical experience before entering on practice.

Moreover, partly from this cause, and partly from the mutable character of modern society, the young physician or surgeon never succeeded so fast, as now.

The future is full of hope. Knowledge advances. Hygiene and preventive medicine prolong the average of life. Zymotics are to be stamped out. Bacteriology is to revolutionize therapeusis.

We, who have once ploughed the land, look back across the furrows of time, and gather new hope, as we see the renewed greenness of the fields of science, cultivated as they have never been before.

Only would we insist on the caution begot of experience, on the value of the past.

Let us advance firmly and with a confident heart, still holding fast to that which is good. The magnet does not vibrate. The sun and stars are eternal in their courses. Nothing can deflect from his course him who studies, hopes, believes, works.—*Bul. Harv. Med. School Asso.*

## EDITORIAL.

### INCREASE OF INSANITY IN THE UNITED STATES.

Statistics are notoriously elastic; that is to say, almost any proposition can be mathematically proved either true or false according as figures may be manipulated. At the same time statistics afford us the only method of measuring any proposition of very extensive and general scope.

The Government decennially takes an account of stock in order to gain information regarding itself. Now the census has been made to include items pertaining to public and private affairs, so that one may almost say the very hairs of his head are numbered. But the census reports can only be regarded as approximate estimates, and not accurate statements of the conditions dealt with.

The last census of the United States indicates that the increase of insanity has been proportionably much greater than the increase of the population. This rapid increase is more accurately demonstrated by the periodical reports of institutions for the insane and of public officials who take exact cognizance of the insane under treatment or care, at definite dates, from year to year. These reports show clearly that the number of the registered insane has much more than doubled during the past two decades, while the census shows for the same period that the population of the United States had gained about sixty per cent.—being about forty millions in 1873 and about sixy-five millions in 1893.

The proceedings of the Conference of Charities at Chicago show by official reports that in many of the States the increase of the registered insane has been astounding. Thus in Rhode Island, where, in 1873, only 150 persons were in the chronic insane asylum, there are now some 600—four times as many; though the State population in the twenty years had gained only from 235,000 to 370,000—sixty per cent. In Iowa the count of the insane went up from 600 in 1873 to 2,385 this year; the population in that period having gained from 1,320,000 to 2,000,000—or fifty per cent., but the insane having more than trebled. In Kansas the population rose from 475,000 in 1873 to 1,500,000 in the present year; but the insane reported twenty years ago were but 200, where now

they are almost 1,500. In New York the gain of population was from 4,600,000 in 1873 to about 6,500,000 this year—less than forty per cent.; but the insane have risen from 7000 twenty years ago to more than 18,000 this year, gaining nearly one hundred and sixty per cent., or four times the general rate. Ohio, with an increase of inhabitants from 2,800,000 in 1873 to 3,800,000 now, apparently shows an increase of her insane from 3,147 to 8,500—one hundred and seventy per cent. as against thirty-six per cent. gain in the total. But of all the States Illinois gives the greatest proportionate surplus of insanity; for while her population gained from 2,700,000 twenty years ago to 4,050,000 now,—fifty per cent.—her registered insane, according to the Conference report, went up from 642 to 4,867, or a gain of six hundred and sixty per cent.

These reports, of course, are only in general terms, and may be full of unrecognized errors; but they are correct enough to evidence the general fact that insanity is on the increase.

The causes of this increase are numberless and are not restricted to any locality or, indeed, country. It is believed that a similar increase is shown among all civilized nations. These facts are of direct interest to physicians by virtue of their profession; especially so is the conclusion that seems inevitable—that chronic insanity is virtually incurable.

## CORRESPONDENCE.

EDITOR OF THE MEDICAL AND SURGICAL REPORTER:

I have read attentively the letter of your correspondent in the issue of December 23, on "A plan to remedy the dispensary abuse," and I regret to find no suggestion as to a remedy for the abuse.

Your correspondent dismisses the subject with the assertion that "there is no reason why the general management of the dispensary system should be disturbed," thus leaving the matter just where it has been for a long time, and if the members of the profession are satisfied, there is no reason why the writer should not be.

The subject is not one in which the writer is *personally* particularly interested, and his only motive in considering the matter at all was in behalf of his professional brethren.

It is all very well to clamor for reform, but if we stop there, what have we accomplished?

What we want is a practical plan upon which to *work* for the desired reform, and it was with this view that "A plan to remedy the dispensary abuse" was proposed, with no idea that it was perfect!

It seems to some after carefully reading the scholarly letter of your esteemed correspondent, that our proposed plan with modifications and elaboration, might be made to cover many of the abuses which he so ably and truthfully portrays in his letter.

There can be no doubt that we need "organization" and "discipline" to accomplish anything, and it was with the hope that our medical societies would take the matter up for consideration, that we ventured our suggestions. We still hope for criticism of our plan and for suggestions as to a better scheme by which the profession can be helped.

Nothing but prompt and decisive action will be of any avail, and who will take the initiative?

It is easy to exclaim, "*impractical,*" but let each one propose a better plan, then we may expect from the multitude of counsel to formulate something that will meet the case to the satisfaction of all, but we cannot anticipate much help from those who are selfishly interested in continuing the abuse. I hope to hear from more general practitioners in regard to the subject which should be of great interest to them.

Fraternally yours,

ALFRED K. HILLS.

December 29, 1893.

# ABSTRACTS.

## SICKNESS AND PAUPERISM.

L. L. BRYANT, M. D.*

There are over 8,000 histories of families who have applied for public aid on file in the office of the overseers of the poor in this city, This represents 24,000 names, in round numbers which appear on the pauper books of Cambridge. To this list, names are continually being added at the rate of 1,500 a year. What are we, as a Society, doing to prevent this? The question has often been asked me: "What are you doing?" and I have many times propounded the same question to myself. This paper is written in the effort to reply. In the month of May, 1883, ten years ago, I was elected to the office of Assistant City Physician. The said office was created December 1, 1880, to enable the local Board of Health to conform to statutory law and yet retain the incumbent City Physician, Dr. Henry P. Walcott, a man occupying an honored position in the State Board of Health, and standing deservedly high in the respect and esteem of the people, and of this Society, of which he is a member.

My predecessor, Dr. O. C. Turner, a most estimable man, died in October, 1892, of typhus fever, contracted while in harness; and during his illness, and subsequently until my election the affairs pertaining to the office were satisfactorily conducted by my friend, Dr. Wetherbee.

With a nervous organization particularly susceptible to external influences, and with absolutely no knowledge of the refinements of modern economics as applied to the poor, I sought and found the office which I still occupy; and my only qualifications were a fair knowledge of general medicine, and that experience which usually follows the first few years of practice subsequent to graduation.

The gaunt, hollow-eyed, cadaverous poor, having nothing and wanting everything, I knew nothing about, and as little what to do for, or with. Entering the service of the city under the circumstances, and in the conditions mentioned, I first made myself acquainted with the duties prescribed by the city ordinances.

I found the office of the overseers of the poor to be the abiding place of one of the most perfect systems with which I had ever been made acquainted, with its thousands of histories of individuals, each one necessary to the proper registration of an applicant for aid and the establishment of a legal settlement, numbered, indexed, and filed away in bound volumes. I found in this office all the usual machinery and labor-saving devices necessary to the conduction of a large business, and presided over by a secretary, D. P. Muzzey, devoted to his work; and apparently constantly employed. I found that all appeals for assistance must be made to this secretary, who was empowered by the Board to dispense the city funds at its command as it deemed for the best interests of the applicants, and then to so manipulate the official machinery in the interest of the city as to secure from the various cities and towns wherein they had resided long enough to acquire a settlement, a monetary equivalent for everything paid out and for all services rendered. I found that the fixing of a settlement on some other city or town was one of the most important duties of the office, and required the service of a so-called "visitor," who, likewise, was apparently constantly employed. This labor necessitated calling on the applicant, asking for, and recording various personal questions, searching city and town records to prove the truth or falsity of his or her statements, and, in general, the making of such a return to the office as would enable it to form as accurate an idea as possible of what he had been, what he was, what he wanted, and how we are to get anything back?" I found that the secretary was the confidential clerk and advisor of the Board, the disburser of supplies, and came into more intimate relationship with the Board, the poor, and the general public than any one else, and conscientiously performed his duties.

The visitor, Vespasian Danforth, enjoyed the distinction of being considered one of the best versed men in pauper law

*Assistant City Physician of Cambridge, Mass.

in the State. Both of these public servants were ever on the watch for fraud, and worked the machine, seldom allowing sentiment to change the order of its working. Not but they were susceptible, but experience continually taught them that yielding to it was an unprofitable indulgence save as a reflection from the Board. I found as a working formula that the overseers of the poor expected me to visit such of the poor of the city as the secretary should direct, prescribe for them as my judgment dictated, and to suggest to the office anything which I might consider to be the policy of the city to do in the direction of relieving their sufferings and distresses, or tending towards making them better law-abiding and self-supporting citizens.

Of all classes, the poor seem to be the one easiest to prescribe for, their wants being few and simple, and one's mistakes are so easily buried. I went into the work largely for the salary I was to get. I did not love the poor, that I can remember, except in an off hand sort of way, and I am not certain just how much I have acquired; but I soon found that there was something more for me to do than to issue dogmatic instructions as to medicine and diet. These must often be furnished; and not alone diet and medicine, but everything my patient's condition sets up within me the want for him to have, but there was more than this.

The labors of the Board, with which I was connected, were not only directed toward relieving paupers, but toward the prevention of pauperism. The more I became acquainted with the office and with its efforts in this direction the more apparent became the responsibilities which I had assumed; and often, as the magnitude of the efforts of others in charitable work have become known to me, my own have seemed so futile, that a morbid sense of my unfitness for the work that was gradually unfolding itself oppressed me. To-day, all the Utopias of which I may have dreamed, are vanished. I feel that I have acquired what the boys call a "crust," from off which smiles, tears or curses alike glide, and if ever unpleasant reminiscences assail me I pull myself up out of the pessimistic slough, with the comforting thought that I have done my duty as I have seen it, and have earned my salary.

The man in private practice has his pensioners to whom he gives or withholds according as his emotional centers are affected. Nowhere have I found such tenderness, devotion, sacrifice, and forgetfulness of self, as that exhibited by the members of the medical profession, particularly for the worthy poor; those unaggressive individuals whose morals, or "rules of conduct considered essential to social existence," appear like ours and have not altered under poverty's pressure; those who suffer and are still, and who practice virtues we do not ourselves possess. This is often, however, but the chrysalitic or transition stage preceding their development or degeneration into the unworthy class.

The unworthy poor are those who do not approach or appeal to the average medical man as he fondly imagines that he would, were he in the same financial condition. There is an aggressiveness and an insolence about them that is repellant, and which gives one the impression that the same force economically applied would make them independent of others' assistance. But the law knows no such distinction; sickness levels both to the same plane, and as the medical officer of the city the fact that I am to care for any one being established, I have nothing to do with his morals except where their defection is the cause of his disease, and must use the same circumspection for all alike.

Upon going out into the homes of the poor, I found there the hard, coarse, hellside of life. I found as types, the nice old lady who wouldn't for the world have her friends know that she felt obliged to have the city doctor; the tired-out, exhausted, poorly-feed, discouraged laborer; the thin, hatchet-faced mother, daily rubbing her very life into the washboard, while the father stays at home and minds the babies; the broken-down beat and bummer, with his trembling muscles and his protestations of sobriety; the sick infant, left to the care of one scarcely older than herself; the dirty, lousy syphilitic; the consumptive and chronic rheumatic, waiting for and looking forward to death; the criminal imbecile, fool and insane man; and the little children prematurely aged and kept at home at scullion's duties. Seldom I found the square, honest, upward energetic look, but oftener, the inert, downward, sneaking, leering glance, with the light reflected from the white of

the eye. Here a woman asserts that she is sick, that her husband has rheumatism, or that her child has a contagious disease, that I may be induced to request of the office, fuel or groceries. Here is an intelligent man of the genus tramp. I met the same man last year, and the year before that. The nights are getting quite cool now, and he concludes that it is about time to go into winter quarters. Leisurely he makes his way to the office, and informs the officer there that he would like to go to the almshouse. Asked why he does not go to work he replies with an injured air that he has a pain in his back and cannot work. The officer demurs. The man grows persistent, and is finally referred to the doctor. The injected superficial veins and his general tremulousness tells their own story; but what about the pain in his back? Is there one of you here who is able to tell whether he has, or has not, a pain in the back? You are morally sure that he is a fraud; but who of you having the power has the courage of his convictions, and will say to that man, "No." No; public sentiment has not reached that stage where it will support any such decision, and we think again, and we find that it is true that he is not quite "up to concert pitch;" that he does need a little straightening out; and a doubt begins to frame itself that we have all the factors relating to that pain clearly before us, and the man goes to the almshouse.

Here the best that the house affords is his; food, clothing, bedding, pipes, tobacco, and that luxury of the modern hotel, a smoking room. Here in this steam-heated shelter, he whiles away the short winter days, sleeps through the long restful nights, grows fat, and perhaps, when the snows have gone, and the spring is well advanced, he ties up clothes in a bundle that he did not fetch with him, tells us that he has found work, and bids us adieu.

It is no state secret that public officers are largely at the mercy of a class of persons made sharp, keen and desperate by their fancied necessities, who are more difficult to manage than criminals because they are not under the ban of public censure, but hiding under the wings of public sympathy are in the position to dictate and the officers must obey. That this is true abroad as well, is asserted by Josiah Flynt in the October *Century*, who says of Germany, the home of the most-advanced public efforts relating to pauperism to-day: "With all its groans under taxes, military and otherwise, it nevertheless takes upon itself voluntarily the burden of the voluntary vagrant—the man who will not work," and after giving a resume of the various methods and institutions employed, he adds: "But the man who will not work passes through these institutions as freely as the man who will."

And now, what shall I do with my patient? The therapeutics of pauperism, complicated with sickness, is somewhat different from that employed where treatment is confined to sickness alone. Both are morbid conditions, and either or both may be inherited, or acquired, or contageous. Both must often be treated at the same time, because if the treatment be limited to one, fatal results may accrue from an aggravation of the other. Together they make up a combination that in spite of the prayers, labors, study and money used and continually being used, is frightfully on the increase. When I do not know what to do I fall back on the machine. When I can care for my patients at home, I do so. When it is a question of hospital or almshouse, I send him to the almshouse. Why? Because it is cheaper. Surgical cases go to the hospital, because they have the appliances, and can command the skill which I do not not possess.

As the years have gone by, I have been led to look into the "springs of man's action," in search of the causes of pauperism, and for additions to my armamentarium. I have found the truth of Bastiat's observation, that all economic movement may be resolved into "wants, efforts and satisfactions," terms correlative of those of the reflex process of ideation; perception, comparison and action. Want, according to Gunton, is "such conscious need of an object that its absence will cause sufficient pain to induce the efforts and sacrifice necessary to its attainment." "Want is the sole motive, and the only measure of effort, for no more effort is ever put forth than is necessary to secure satisfaction. Until a desire becomes so intense that more pain is produced by its non-satisfaction than will result from the labor and sacrifice involved in its gratification, it is not an economic

force of want, the need to consume being too weak to impel sufficient effort to produce."

I found that man's efforts tended towards the achievment of satisfactions that are "customary, and therefore demanded" by the best livers among those with whom he associates, the sum of which constitutes his "standard of living."

I found that perceptible advancement in one's standard of living was not a matter of days or months, but of years; and that any attempt to force its growth met with waste.

I found that the standard of living of the poor with whom I came in contact was not mine, was best ascertained by comparison—not with mine—but with those of a social equality with them, and that their efforts were then more intelligently directed along economic lines.

I found that history teaches that public aid does not strengthen but weakens, and breeds the disease called pauperism.

I found that it was not expected that this people should remain paupers, but that their necessities should force them to continue their efforts to keep up in the race.

I found, as Stoddard puts it, that "not what we would, but what we must, makes up the sum of living," and that sickness, sighs, tears and groans were not economic forces, but media through which one's ineffectual desires and efforts were communicated to others.

Physical disease is a common foe, without sentiment, smiting alike the rich and the poor who disobey the inexorable laws of health. Money will not propitiate it, years of penitence and years of prayer have not stopped its devastating onward march, and it is only when we add the sick man's ineffectual desires to our economic wants, and let our strength compensate for his weakness in a common struggle for a common satisfaction that sentiment is of value as a therapeutic agent. It is not the empirical sentimentality that gives birth to flowers, ice cream or religious tracts, but the kind that reaches down, grabs you by the hand and stands shoulder to shoulder with you in a *fight* with a common enemy.

I have found the same is true in the treatment of pauperism. It is not pity that comes in with tears, sighs and groans with which to fight tears, sighs and groans, but that coming with the trumpet call to arms. There is a sentimentality, and affectation born of ignorance, money and fadism with which we all are acquainted. It looks right, but it rings flat. It takes a man up, toys with him until he ceases to be a plaything and refuses to be wound up, or to run right when he is, then it tires of him, and he is told that if he wants any more assistance to apply to the overseers of the poor. What can the poor devil do? Go to work? Where? What is the incentive to work? No, he has eaten of the tree of knowledge, his ambition and energy are sapped, his moral tone lowered, he cries inertly: "God help me, what can I do?" and he lets his wife and children work. He applies to the overseers of the poor and contracts pauperism. His children are taken sick. He is informed that he can have free medical attendance by application to the city doctor. Is his condition improved? Is the material condition of his family improved? Not as I see it. Down he sinks, lower and still lower in the social scale until, as the years come and go and his children reach the age when they should be self-sustaining, they too think and act along the same lines, and have an incapacity for economic effort. A glance at the histories on file in the office of any board of overseers of the poor will show this to be true, as will also a perusal of the history of the notorious Jukes family.

And now, what can be done to prevent a continuance of this state of affairs? Make no distinction as to worthiness or unworthiness, and keep the people from going to the overseers of the poor. That the men of some sections of the city are doing this I know, from the few calls I get in their locality.

As physicians we can not afford to shirk the responsibility which is clearly ours, by every law of scientific and human right.

We are scientists, striving to look through the maze or error and to discover the truth.

We are philanthropists by virtue of our profession, intrusted with the lives and the material happiness of our fellows, poorly paid for our services even by the wealthiest, and looking forward to the close of life, not with the expectation of leaving a large account to our descendants, but an example for their emulation.

We are optimists, too, ever looking for the best principles that move mankind. We come into closer relationship with humanity than pastor, priest or law-giver. Ours is the opportunity possessed by no other body of men, to inculcate those principles of thrift and independence which are the essence of true manhood, womanhood and American citizenship.

The individual study and applied efforts of each in a few instances will produce better results and more lasting satisfaction than with many.

In my own case I aim at quality and not quantity. I am not at all anxious to present a list of a large number of patients in my annual report.

When a man comes to me to be inoculated with pauperism and informs me that such a doctor always attended his family, but that he owes him a bill and is ashamed to ask him for further assistance, I send him at once to his physician; and I instruct him to tell his doctor his whole story, concealing nothing; and then to say to him: "Doctor I have no money, but just as soon as I can get work I will pay you a little at a time until my bill is paid." I have never know such an effort to fail.

A little story of Marshall Wilder's I sometimes use a therapeutic agent: "Two frogs fell into a pail of milk. One exclaimed: 'Help! Help! I sink! I drown!' The other answered gruffly: 'Kick! Kick; you little devil! Something will surely happen.' The first one continued to gasp and moan, and finally sank out of sight. The other kicked and kicked until nearly morning, when the milk having been churned to butter, he waked out into dry land."

DISCUSSION.

Dr. Morrill Wyman said he had not seen as much pauperism as the reader, yet he had had considerable experience with it. He told of one case rather remarkable, where the father a miserable fellow, became a pauper and the succeeding children, making three generations, followed his example. In the early days of practice there were few foreigners in Cambridge as compared with the present time and there was less pauperism.

Seeing a number of lazy looking fellows loafing about a corner, only a short time ago, he accosted one who was smoking and asked how these men obtained a living; when he received the reply that their parents went out to work and their mother took in washing. When asked what was to become of these men the fellow replied: "They will bring up in jail if they are lucky enough to escape hanging."

Dr. Hoarce Marion said the reader had presented in a forcible and illustrative manner may stubborn and stony facts. The subject is a broad one to grasp on which little literature has been published, and with foreign countries pouring in a constant supply of pauper, one of great moment for the welfare of this country. It is difficult to say what is best to be done, but it is certainly sure and important that patients should be kept away from the overseers of the poor.

The emergency societies are doing much to prevent the development of pauperism. Their method is to practically give them the articles they require, but at the same time to make them work and think they thereby earn them. A great part of the work Overseers of the Poor consists of the investigation of settlements; by this means a certain amount of money is refunded from the township whence the pauper came.

Dr. Taylor said in a few instances he had sent patients to the Overseers of the Poor, and thought it had a stimulating action, effecting the patient to do something for himself. He did not like to attend non-paying patients who live at a distance, neither did he think it right to send such patients for care to other physicians, although he knew instances where such cases paid something to the other doctor.

Dr. Clarke said when he came across long, tedious cases that required much care and medicine he usually referred them to the city physician. With poor patients who cannot pay, he is in the habit of making them do service of some kind in exchange for his advice, and thinks in many instances it has a good effect. Certain cases are too lazy to work. In Boston, certain institutions are in the habit of making applicants for meals work—sawing a quantity of wood, in compensation for the food given them. Some men will work hard and others prefer to go without a meal rather than work and earn it. He thought a similar line of action to this might be taken in Cambridge, and is of the opinion that most of the foreigners imported here are of an industrious nature and not inclined toward pauperism. The

West is largely built up of this class of people. The greater number of paupers are American born, and they form the worst class. Most foreigners come over here with higher motives than pauperism; they come to better their condition, and many instances might be quoted where they become prominent citizens, such as one he had encountered this summer at Chicago.

Dr. Norris differed from this latter view; he thought "the microbes were imported," and that paupers originated, at least, from the foreign element.

Dr. H. P. Walcott said his relations with the Government did not give him the intimate knowledge of the poor which Dr. Bryant possessed. He thought Dr. Clarke's statement worth consideration; it is certainly true that the worst class of paupers are those educated in pauperism, and that we have educated many of our citizens in this respect. We do not import many paupers now because our ports are guarded against the landing of this class, and a large number who come over are recognized as paupers and sent back. State and municipal aid are unfortunate for the poor, as such aid tends to make paupers of them.

DR. VAUGHN: Municipal and State charity is an irremediable evil. Brooklyn has cut off all outside aid; the burden is carried by voluntary organization. Public relief is not charity; it is compulsory to meet an evil that can not be helped. The taxpayer supports it. The associated charities and Overseers of the Poor work so closely together that the latter turn all cases over to the former for investigation. With more or less help from organizations to substitute the work of the Overseers of the Poor, he thought the public would be relieved of much of its pauperism; and he hoped the time would come when by the combined effort of the associated charities and other similar associations, the work would be entirely removed from the Overseers of the Poor.

It is now arranged so that a person can have his or her name erased from the books of the Overseer of the Poor, by paying back such sums as have been given.

Dr. Dow rarely sends a patient to the city physician; he explains that it makes paupers of them and usually they wish to avoid this condition, preferring to pay him something for his service. He questions the wisdom of sending a visitor to the poor, because they are received as a distinguished visitor and not as a friend. The associated charities makes the poor reform without giving them much.

Dr. Lloyd thought the consideration of the poor at this meeting is in their relation to sickness, a complication of pauperism, and a very proper subject to be brought before the medical profession. The pauper is a person in a chronic condition of mental and physical weakness, and requires to be carefully studied, like crime or other diseases. The sick poor must suffer until means are found to obviate the condition of pauperism. This is an evil of civilization, and increases in ratio to the wealth and intelligence of the people. The condition may have come from the mental state of antecedents which have been introduced into this country, but not found among the earlier settlers. This foreign element diseased with crime, immorality, etc., give issue that are dealt with as American born citizens, live in and infect cities, cause crime, poverty and pauperism. All good citizens should act in conjunction to prevent the imposition of these people. The best way of dealing with this class is to make each individual believe he must be self-supporting; the poor man must be taught that he can and must do something for a living unless physically diseased.

DR. Mahechnie thought it did harm to help poor families; we are guilty of doing them an injustice when we do not make them pay their debts. There are few paupers in West Somerville, because the physicians there render such aid as is required of them.

Dr. Henry O. Marcy considered intemperance a great cause of poverty. He asked if the hard times had not increased the work of the overseers of the poor among the worthy poor. There are many Italians of the North end, Boston, who have less comfort than cattle. "He considered "educated men expensive animals."

Dr. C. C. Foster thought that children's homes contributed to the list of paupers, because the children were not taught how to work and earn a living.

Dr. Morril Wyman asked if children that had been placed in the almshouse had any desire to return home?

DR. FOSTER.—No; they want to stay, and while there they hear the talk of the older paupers, which is vile and perfectly horrible for the ears of children.

Dr. Bryant in closing the discussion said that children in the almshouse were associated with old women and bummers; do not get the care or instruction which they should, become and remain paupers. The education of these poor children should be looked after. He considers the medical profession should be responsile for the well-being and morals of all homes into which it is brought.

A district nurse is of great value, to instruct and make homes brighter and cleaner.

Seventy five per cent. of paupers are of Irish descent; next come the Western Islanders and Portuguese. Poverty comes from intemperance and intemperance often comes from poverty; the poor wish to drown their care and sorrow in drink.—*Jour. Amer. Med. Ass.*

## THE PROVINCE OF EXPERT TESTIMONY.

A clear exposition of the province of expert testimony is made by the Supreme Court of Jersey in Koccis v. State, just reported. In this case, attempt was made to prove that a foreigner who spoke broken English words of the same purport and meaning. This, it was held, was not a subject for expert testimony. The testimony offered, if admitted at all, the court said, would be received not as an expert's opinion, but because it came within that class of cases in which a witness may state the inference drawn by him from facts within ordinary knowledge occuring in his presence.

Familiar instances in which testimony of this kind may be given, the court says, are: whether two people were in love; whether a man was sick, or dazed, or despondent, or drunk; whether a dog was savage, or a horse gentle,—and, in general, any matter touching physical or mental manifestation or appearance, as well as all questions of identity, resemblance, duration, distance, dimension, velocity, noises, smells and many other matters where the inference drawn by an observer is commonly recognized and received as an equivalent for the congeries of facts that produce it. But testimony of this class, however, so far from being related to expert proof, rests upon diametrically opposite grounds.

The expert witness is one whose possession of special knowledge renders his opinion admissible upon a state of fact within his specialty, without regard to the manner in which the facts are established, and without requiring that they should have come, in whole or in part, under the personal observation of the witness; whereas, the sole ground upon which a witness may give an opinion as to the matters of ordinary knowledge is that they not only came within his personal observation, but that they come into proof so blended with the opinion to which they give rise that it is receivable in proof as a substitute for a specification of the host of circumstances that called it forth.

A failure to observe this distinction results, at times, in the offer of an ordinary witness to give an opinion calling for special knowledge, merely because he has had actual observation of the facts, and at other times in the offer to prove an opinion upon a matter of ordinary knowledge arising from assumed facts, by a witness who has not himself observed them, upon the ground that he is expert upon the special subject. In either of these classes of cases the proof must be rejected; the rule being that mere opportunity will not change an ordinary observer into an expert, and that special skill will not entitle a witness to give an expert opinion when the subject is one where the opinion of an ordinary observer is admissable, or where the jury is capable of forming its own conclusion from facts susceptible of proof in common form.—*Jour. Amer. Med. Assoc.*

SHE—"What do you really think of me?"

HE (with sudden enthusiasm)—"What do I think of you? I think you are the sweetest girl I ever loved."—*Ind. Journal.*

## ATAVISM INVOLVING THREE GENERATIONS.

Dr. Deane, of San Francisco, offers an instructive and interesting object-lesson occurring in my own experience of a family which I have had under observation for nearly twenty years.

In 1849, a young man and young woman were married in the Atlantic States; husband, sea-captain of good old stock, a man mentally above the average, with some literary requirements; a drinker, and I believe syphilitic; died a paralytic in 1876. Wife of good family, also, *petite*, negative disposition, moral qualities not highly developed, refined, still alive. To this man and this woman were born, from 1850 to 1868, eight children, four boys and four girls. Let us follow the lives of these children, beginning with the boys. The first born—a man now in the forties—has always been a good-for-nothing, a drunkard, associating with a class far beneath him, mentally and physically below normal; has never married. Second boy lost at sea. Third boy mentally and physically below normal, died of phthisis a few years ago. Fourth boy, mentally and physically the same as his brothers, appears to be developing phthisis, committed a murder a few years ago, and got off on the plea of self-defense, through influence brought to bear on the authorities. Married a woman far beneath him socially, has two children, oldest with dolichocephalic head and very delicate; the youngest I have not seen. Altogether, he is not a citizen that the community need be proud of. So much for the boys.

First girl, a woman about forty, developed early, physically and mentally, sexually at a very early age. Commenced running about at nineteen, French dinners, etc., with all their accompaniments; after several months of this kind of life she accidentally dropped into the hands of a man of the world greatly her senior, who took a fancy to her and saved her from herself, gradually drew her away from her evil associates, developed her mentally, and she promised to go through life a faily respectable woman. In 1881 she married a man in good social position, who gave her a home with many of the luxuries of life, but the hereditary curse followed her, she began to change about two years since, and that appeared to light up again her sexual nature, like the last sputter of a dying candle. She conceived a passion for a young man, a friend of the family, fairly threw herself at him and never let go until she had seduced him—a clear case of nymphomania. There came very near being a tragedy in consequence, the lover not suspecting to this day how near. The only redeeming point in this woman's life is, that God has denied her the power of perpetuating her kind. Perhaps when the menopause has passed she may settle down, although there appears a tendency in her to develop viraginity.

Second girl married early; very delicate; has had three children. First child an idiot; two children living, both below normal physically, with dolichocephalism strongly marked; mother developed during the last few years exophthalmic goitre; had her under treatment for some months and she improved on anti-syphilitics. Third girl died in infancy. Fourth girl is now about twenty-four and is physically the superior of any of the other children; there was a period of eight years between her birth and the last of the others; she is tall and well formed. How this girl will develop remains to be seen; mentally she has yet shown but little, but I think I begin to see some progress, and I should not be surprised if, perhaps, she was to redeem the family. An aunt of these children was insane. Dr. James Weir says, in an article of the *Medical Record*, "the phenomenon of atavism is more apt to occur in feeble types than in strong, healthy and well developed types." Here we have three generations to examine, each one apparently worse than the last; however, there is a law of compensation which luckily carries off these types early in life, and which seems to deny them the same prolific power of reproduction the healthy and well developed types attain to.

Certainly these people are hardly responsible for their acts any more than the hereditary drunkard. It is a disease, and they should be surrounded by influences from their youth which might counteract the unfortunate results to follow, not only to themselves but to those about them. Above all should our sons and daughters inquire carefully about the antecedents of families before becoming members thereof.—*Pacific Med. Jour.*

# SOCIETY REPORTS.

## SECTION ON ORTHOPÆDIC SURGERYOF THE COLLEGE OF PHYSICIANS OF PHILADELPHIA.

(*Meeting December 15th, 1893.*)

The discussion of the subject "Torticollis" was opened by a paper entitled

SPASMODIC TORTICOLLIS AND ITS MEDICAL RELATIONS,

By Dr. F. X. Dercum (see page 39), followed by a paper by Dr. Wharton Sinkler on

THE TREATMENT OF SPASMODIC TORTICOLLIS BY CONIUM. (See page 46).

Dr. H. Augustus Wilson exhibited a patient, aged five years. Two years and four months ago, patient is said to have had quinzy. Mother says the child suffered continuously for four months, which appears to cast a doubt upon the correctness of the diagnosis.

The following history was obtained from the mother: At the very beginning of her complaining of sore throat, her neck was stiff so that she could not move it in any direction. There was decided pain throughout chest and arms. Her sleep was disturbed. Upon arising in the morning, it was necessary for the patient to support both sides of her head with her hands on account of severe pain. This condition lasted for four months. Four months after she first noticed the crooked head, the patient came under observation at the Jefferson Hospital.

The diagnosis of caries of the upper cervical vertebræ was arrived at, four months after the first appearance of wry-neck, by the presence of a most marked muscular rigidity around the neck. The muscles in the upright position were tense and yielded only upon the patient being placed in a recumbent position, or when the head was well supported by the surgeon. The sterno-cleido muscles were in a state of relaxation when the patient was recumbent.

A brace was applied, which not only supported the head but maintained immobility and afforded protection, which she wore continuously until one month ago when it was removed. During the last two months of the use of the brace, it was modified so as to permit beginning motion of the head, but restrained the tendency of the head to turn to the right side.

At this time the following observations were made: Head turned to the right,—1½ inches from symphysis of lower jaw to line of mid-sternum. Flexion and extension not easily performed; rotation of head easily to right side, but motion to left impaired by right sterno-cleido-mastoid. When the head was so turned without effort on the patient's part, there was but slight over-action of the right sterno-cleido-mastoid. When the head is thrown backward, both sterno-cleido-mastoids appear alike, and the same obtains when the head is bent forward on the chest. Left shoulder carried a little higher than right. There is a slight lateral curvature principally noticable in dorsal region.

No movements are apparent in second, third, fourth, and fifth cervical vertebræ, which are less prominent than normal, while the sixth and seventh and the dorsal vertebræ move freely. The brace was adjusted towards the last so as to allow a little freedom of movement before it was taken off—about three months time was permitted from the time it was rigid to its removal.

Since the discontinuance of the brace, light gymnastic movements have been permitted, in order to develop the muscles that had become atrophied from disuse while the brace was applied rigidly. Since the head apparatus was made moveable, the patient has noticed a crepitus which was only of periodical occurrence and is now very much less marked than formerly, and appeared to be of the nature of fibrous adhesions.

DISCUSSION.

DR. J. K. MITCHELL: I have very little to say this evening, but should like to report two cases of spasmodic torticollis which present features somewhat different in character from the condition as it usually appears in children, although they were both in young people. My experience has been that this condition is more common in adults, and in them it is exceedingly obstinate to treatment. In children, the fixed form is more common, and either form is much more amenable to all remedies. Operation is more likely to be effectual in children than in grown persons, and this is true, likewise, as to treatment by mechanical measures. Apparatus alone will sometimes effect a cure, as is well illustrated by the interesting case just shown by Dr. Wilson.

My two cases were both in young people; one a man, about twenty, whom I saw in St. Mary's Hospital. He had refused operation, and had come into the medical ward for treatment. He had been handled in all sorts of ways, with drugs and various mechanical measures, without much benefit; nor at first can I say he improved at all, notwithstanding everything that we could do for him, until finally I gave very large doses of gelsemium, with decided improvement, which, however, was not permanent until ice was applied. I did not try conium, which Dr. Sinkler found so effectual in some of these cases; but an ice-bag was kept upon the neck day and night, extending from the anterior border of the sterno-cleido-mastoid muscle back to the cervical spine, as low down as the origin of the nerve supplying the affected muscles. This was constantly worn, as I say, and by it the man was much relieved, the pain and spasm both diminished very much.

The second case was in a young girl and was undoubtedly of an hysterical character, a number of symptoms pointing, as you will presently see, in that direction. She came of a nervous family, and had persistently overstudied at school, which she was obliged to leave on account of the occurence of a violent headache and a general rundown condition, with the exhibition of uncontrollable fits of temper. Her first complaint was pain on the right side of the nose, which extended into the eye, and for sometime at first was limited to this area. It comes on in paroxysms: with some twitching of the muscles of the face, and after it had lasted a few weeks, extended through the side of the face and neck as far back as the spine. It presently began to be accompanied by spasmodic movements of the sterno-cleido-mastoid and trapezius muscles, with some pain in both face and neck. These spasms occurred ten or twelve times a day, and every treatment entirely failed to relieve her. Massage, electricity, drugs,—nothing had any effect. I put her to bed, and on a milk diet, and for the first two or three weeks she grew better. Then the spasmodic movements began again, and during the succeeding month increased in their extent so that she had many times a day, general convulsions, usually opisthotonic. During the attacks, and sometimes between them, she had double strabismus, complete amblyopia, and pupils rigidly fixed in dilatation. At one time, in an access of despair, I bled her, having seen on one or two occasions bleeding do good in hysterical convulsions. We drew some 18 or 20 ounces, and for a week she was much better. Then she relapsed again, and, finally, when her family was worn out, and two or three nurses had been used up in the service, I took her to the Infirmary for Nervous Diseases, left her there with a strange nurse and under the mostly rigid rules of isolation, and from that day she had no attack of convulsions, the pain rapidly diminished and she is now perfectly well.

The case, as I have said, was of course of an hysterical nature, but at least one distinguished physician who saw it in consultation with me, was of opinion that she had meningitis at the base of the brain and would certainly die

DR. J. K. YOUNG: The subject of Torticollis has been so thoroughly discussed this evening that there remains but the mechanical treatment to be considered. A great many mechanical appliances have been proposed, but most of them are unsatisfactory when applied. Torticollis is divided into two classes—congenital and acquired. Congenital cases are those which depend upon deficiency of the cervical vertebræ, malformation, uterine pressure, and adhesion between the amnion and the skin of the face as suggested by Peterson.

The acquired cases may be traumatic, tetanoid, paralytic, compensatory, cicatricial or idiopathic. It is obvious that in paralytic and tetanoid cases no operation is of service.

The simplest form of apparatus is that used by Dr. Ashhurst, and as originally suggested by Little. It consists of a piece of adhesive plaster about the head, another one about the upper part of the thorax, and a firm muslin roller bandage from the chest region on the side opposite the chest and front. After operation the head may be placed in the correct position by means of a plaster-of-Paris bandage. The bandage which I prefer, in all operations upon the head and neck, is the starch bandage, which may be strengthened by strips of a wood bandage and strips of aluminum.

Another form of apparatus is the Minerva collar pattern, which may be made of felt, leather or other material.

The apparatus of Barwell, referred to under the title of "A cheap and simple apparatus for the treatment of torticollis and cervical caries" is the butterfly pattern. It may be made of felt, cut in shape and adapted to the head and neck.

Of the more elaborate forms are those on the principle of Jorg. Of this pattern there are several; the best one is that used by Dr. Schaffer of New York. It consists of an apparatus applied to the back, from which is erected a head piece and a chin rest, and which is attached by a universal joint which admits of its being placed in position. Sayres' apparatus is made upon the same principle.

Dr. Davis' appliance consists of a broad piece of stiff material fitted to the back, with a peculiar shaped head piece which is attached by means of a screw. Other good examples of this appliance are found in St. Germaine's work, page 239, under the title of Minerv de Bouvier and Ernst, of London.

Extension of the head is now used both abroad and in this country in the mechanical treatment of this condition. For this purpose Hilliard's appliance is more elegant than the ordinary extension head piece, and the one I exhibit, is the apparatus used by Dr. Willard in the treatment of cervical caries. When used for torticollis it must be longer upon one side so as to make more pull upon the affected muscles.

To render the subject more complete I should perhaps refer to the method of DeLore of the forcible correction of posterior wryneck. The patient under ether, is placed on the edge of the bed and forcible correction of the deformity is made. In cases where this operation is employed it is necessary to positively exclude cervical caries. I had related to me by a country practitioner, a case in which fatal results occurred in attempting to perform this operation. I have seen many cases of torticollis follow cold, and in such medical treatment has been effective in a few days. After tenotomy, I strongly urge tne use of massage and gymnastic exercises.

Finally, I wish to refer to a number of cases of torticollis occulaire, which I have seen in the past two years. These are due to some loss of equilibrium of the ocular muscles, and they are usually corrected by the application of the proper prisms, the superior or inferior rectus being the muscle usually affected.

When torticollis is due to cervical caries, as it sometimes is, manipulation may produce serious results.

I think I can reply to the question of Dr. Wharton's in regard to the occurrence of mastoid tumor. There are two varieties of cases; in one there is a simple hæmatoma, in the other, rupture of the fibres of the muscle. In the latter variety of cases torticollis occurs. Previous to Whitman's paper, all statements upon this subject were without foundation in fact, and were simply quotations from the writings of Pieffen Bach.

DR. H. R. WHARTON: I agree with Dr. Willard in believing that good results follow operation in cases of fixed wry-neck. I have had some experience in the treatment of wry-neck, both in children and in adults, and I have seen marked benefit result from simple division of the sterno-cleido-mastoid-muscle.

Dr. Dercum mentions asymmetry of the face in connection with this disorder. I saw this well illustrated in a boy, recently under my care at the Children's Hospital, in whom there was asymmetry of the face and skull. I think the want of success in a good many operations is due to the fact that many of them are left without after treatment by apparatus, gymnastics, muscle stretching, etc. If this is not done relapse is sure to follow. In my opinion it is as important as the operation itself.

I should like to ask whether any of the gentlemen present have ever had any experience with wry-neck following congenital mastoid tumor. These tumors are often due to the rupture of some of the fibres of the mastoid in labor and we might therefore look for wry-neck in connection with this accident. A few of the cases I have seen of such tumors have not been followed by the development of wry-neck.

DR. BENJ. LEE: I came here this evening expecting to be simply a hearer and to be instructed, and I need hardly say that in reference to the latter expectation I have not been disappointed. Both the papers and the discussions have been of deep interest. The only point which occurs to me to refer to, is Dr. Wilson's case, concerning which I think we may say that we accept his diagnoses without hesitation. It recalls to me a case which I saw early in my practice, some twenty-five years ago. It was a very marked case of wry-neck in a child about four years of age. On my first examination I pronounced it to depend upon cervical caries. I applied suspension by means of a rachet apparatus attached to the child's high chair, and in a few days marked improvement resulted. Suspension was kept up constantly during the day; she was never allowed to sit up except when the head was supported. In the course of a few weeks, I applied a brace with a head support. The wry-neck entirely disappearrd and the case eventually recovered.

This leads me to say that I believe that in every case of wry-neck in a child, we should examine carefully to see whether there is not caries present. I believe the former is frequently an early symptom, and that long before any deformity of the bones can be detected, we may find wry-neck, resulting from pressure on the nerves at the point of emergence, or from inflammatory irritation of the cord.

The attempt to overcome the muscular contraction in either spasmodic or spastic torticollis, by the sheer force of mechanical appliances, I believe to be very rarely successful. In this connection I would say however, that in many cases I have had good results from suspension, carried on systematically and persistently, and have attributed the improvement to diminished irritation of the nerve trunks. Contracted muscles, I think almost invariably depend upon a central irritation existing at least as far back as the point of emergence of the same from the vertebral column. Dr. Mitchell's case is very instructive and, to me, very interesting. I have been accustomed in all such cases to look for a centre of irritation in the pelvic region reflected to the upper portion of the cord. A rectal or vaginal examination will often reveal a source of irritation of some form either rectal, uterine or ovarian, in the pelvis. If this is relieved, we shall occasionally find to our great surprise and delight, a diminution of the central irritation with complete relief of the reflex affection.

DR. F. X. DERCUM: I do not deprecate tenotomy in fixed wry-neck; in spasmodic torticollis, however, it is certainly little more than a makeshift expedient. In regard to the tumor noted in the sterno-mastoid muscle in infants at birth, it is sometimes due to hæmatoma, sometimes to tear and inflammation of the muscles. When tears occur, fixed wry-neck is very apt to ensue. I think that we ought to be more careful in speaking of our results; cases of spasmodic torticollis are often reported as cured when they are only relieved. Very often indeed, we find a case recorded as cured and find that the account ends by stating, "In six months a slight return of the spasm occured," or "A slight movement of the head only could be observed," and other expressions of like purport. Certainly while drugs, such as gelsemium, conium, and various surgical measures give marked relief, they generally fail to cure absolutely.

DR. J. HENDRIE LLOYD: In discussing the pathology of wry-neck it seems to me that it might be wise to pay more attention to the condition of the muscles; I know it is not the fashion to look for the possibility of this disease in the muscles either in the fibre or in the sheath. I have no scientific data upon which to found a statement that wry-neck is a myopathy, but it seems to me to be reasonable from the fact that this disease is not associated with any particular nerve trunk, but is distributed through irregular muscle groups.

It is popular to attribute all muscular involvement to central disease, which necessarily eliminates myopathia. I do not myself believe that we are on sufficiently firm ground to positively assert that all these troubles are located in some form of meningitis, or irritation of the nerve centres. In

recent years it has been found necessary to remove several diseases from the groups of central disease and to place them among the myopathies. This may yet have to be done with wry-neck.

I was much interested in Dr. Mitchell's case because it exhibits a not unusual form of hysteria. Hysterical torticollis has been described by French authors. It is simply one of the varieties of hysterical contracture. In his case the convulsive phenomena, the contracture, the fact that the patient was cured by isolation, are all very characteristic of hysteria.

DR. DEFOREST WILLARD: Dr. Dercum has spoken of the unsatisfactory results of myotomy of the sterno-cleido-mastoid muscle. While I grant that in a considerable number of cases myotomy does fail, yet in many instances it does give permanent relief. I have seen cases in which there has been no return of the spasm for fifteen or twenty years and this may be called permanent cure. There are a certain number of spastic cases which cannot be relieved by this operation, but in inflammatory troubles excellent results can be obtained from myotomy. I advise first, medical treatment; if it fails, then mechanical measures and myotomy; then neurotomy.

In regard to the question of subcutaneous or open section. At the present time we are much more inclined to the open method since there is less fear of sepsis than formerly. In a female, however, a large scar is annoying and in girls I perform subcutaneous tenotomy when it can be done with absolute safety. I make the puncture with a small oculist's knife so as to avoid the entrance of air even, should a vein be wounded.

In many cases if the sterno-cleido-mastoid is firmly stretched, and if a very blunt tenotome is carried along the posterior face of the muscle, there will be no injury to the vein and the muscle can be entirely severed without danger to other structures. If such division is not sufficient, the mastoid insertion is also divided, and abundant correction is secured. Gymnastics and muscle stretching should be practiced for a long time.

I recently saw a patient, a young girl upon whom I operated three years ago; her neck was in absolute straight position, and it was very difficult to decide on which side the operation had been performed. She had had continued gymnastics.

I have never seen the pleura injured except in one case. It was in a case of Dr. Agnew's, and the patient died from septic pleurisy. I believe that is the only case in this city where death has occurred from such cause.

I think that we ought to insist upon gymnastics being carried on after myotomy. Without it there is little use of tenotomy or nerve stretching.

When medicines, hypodermics, electricity, myotomy fail, I think it far better to excise a considerable piece of the nerve. It is better to attack the spinal accessory nerve high up before it reaches the sterno-mastoid, as then there is no reunion.

Dr. Rhein recently collected for me forty cases of neurectomy and nerve stretching on record, and his figures give eighty per cent. of cases which have remained cured. There was but one death, and that from erysipelas. Thorough excision is an operation justifiable in these cases of spasmodic contraction.

In rotary cases, division of the spinal nerves is, of course, the only operation which promises much hope. Simple division of the spinal acessory would not be of much service, but I do not think excision of all the nerves should be attemped until all other means have been exhausted.

If we are positive that spinal caries exists forcible reduction should be excluded.

---

### The Treatment of Pneumonia in St. Francis Hospital.

Dr. Arnot Spence, states that after an experience with two hundred and twenty-eight cases the writer can recommend the following plan of treatment. In the first place, the bowels should be freely moved with five grains of calomel, well rubbed up with milk and sugar, or if the patient is too weak a more gentle laxative may be employed. A half-ounce of the following prescription may then be given every two hours:

℞ Tr. aconiti..... mxxiv.
Tr. opii camphoratae..... ʒij.
Liq. ammonii acetatis.
Syr. zingiberis..... āā ʒss.
Aquae, q. s. ad..... ʒvj.—M.

Sig. Half-ounce every two hours.

The aconite is given primarily for its effect on the heart and blood-vessels, and thus on the inflamed lung, and secondarily to reduce the temperature. It produces a quieting and slowing of the irritable and rapid heart, and a reduction of the arterial pressure, thereby lessening the amount of blood in the congested lung. It controls the temperature within a safe range, and prevents the marked exacerbations so common in typical cases of this disease. In strong and full-blooded patients, veratrum viride may be substituted for the aconite in this mixture, and used in about the same dose. The paregoric is added to ease the short and harassing cough, which is often such a disturber of rest. The spirit of mindererus acts as a diaphoretic, keeping the skin moist, and in its way relieving the kidneys to some extent. Besides assisting thus to keep the temperature down, it is also a stimulant.

Throughout the administration of this mixture the heart was most carefully watched to note the effects of the drugs, and, all things being favorable, it was continued until the fall in temperature denoted the crisis of the disease. When further stimulation seemed necessary, whiskey was freely given, but never unless it was indicated. The administration of alcoholic stimulants all through this disease, as is frequently done, is a practice capable of doing great harm.

# CURRENT LITERATURE REVIEWED.

IN CHARGE OF ELLISTON J. MORRIS, M. D.

THE AMERICAN JOURNAL OF THE MEDICAL SCIENCES for January. Dr. Maurice H. Richardson, contributes an interesting paper on

**Appendicitis,**

based on a personal experience of one hundred and eighty-one cases. He calls attention to the fact that the deaths from appendicitis are greater than one would suppose because, undoubtedly, many cases are diagnosed as typhoid fever or kindred diseases. The author says that the diagnosis is not always easy, and that it is often difficult to distinguish between this disease and certain others, though the history, with the local signs, is sufficient to make a diagnosis in the majority of instances. With very rare exceptions, a diseased appendix is the cause of all peritonitis, local or general, occurring in males. He says that not infrequently he has found a gangrenous appendix in cases where a diagnosis of internal strangulation had been made by the most experienced men. In all cases of general infection in which the lesion is obscure, the possibility of an appendicitis must be borne in mind.

Pain considered alone very frequently has no direct relation with the usual anatomical seat of the appendix. In making a diagnosis, therefore, the seat of the pain in the first hours of an appendicitis is of no great importance. Tenderness is a more important symptom for diagnosis than pain, inasmuch as this symptom is usually placed directly over the lesion.

The existence of vomiting of stercoraceous material, or of matter of a coffee color, he regards as a very serious symptom. The septic nature of the vomitus must also be taken into account where anæsthesia is used, because in several instances a fatal pneumonia has followed, or a septic bronchitis has complicated an otherwise favorable course.

In regard to the state of the bowels, he states that a large number of cases are accompanied in the first hours of the attack by more or less diarrhœa. In some the diarrhœa preceeds the attack.

As to the time of perforation, he states, most unequivocally, his conviction that in all severe cases of appendicitis, there is a larger or smaller perforation, with extravasation. The first symptoms in severe cases of appendicitis depend upon a perforation, and not on a catarrhal or an ulcerated process in the interior of the appendix. In all cases of severe acute appendicitis, with localized peritonitis, seen immediately, or within a few hours, he believes that perforation already exists, and there is no question of waiting for perforation to take place on the third, fourth, fifth or any other day.

The state of pulse throws little light on the diagnosis, but is valuable for prognosis. In his experience a pulse of 120 in an adult is a grave symptom as to prognosis, depending, as it does, upon a serious constitutional infection. Its value, however, varies with the extent of the general peritoneal infection.

The temperature in this as in other forms of peritonitis has very little weight both as to diagnosis and prognosis. He has discarded the temperature almost entirely as a guide to prognosis. It is an aid to diagnosis, however; but too much stress must not be laid upon it. A very rapid respiration is always a grave symptom, unless it depends upon merely mechanical distention. Caused by septic absorption its existence is of the gravest import. In a certain percentage of cases it is due to some complication in the lungs.

Where distention exists, the abdomen should be carefully auscultated for evidence of intestinal action; for even in some cases of the greatest distention there is no paralysis of peristalsis. The existence of distention dependent upon a local infection is of the gravest import. Whether due to portal thrombosis or to local infection, with simple paralysis of peristalsis, no system is of more importance in the diagnosis and prognosis of the disease than a distended abdomen, accompanied by vomiting. Death almost always follows. The existence of sounds of intestinal action are not only reassuring but call for the exhibition of cathartics and the rectal tube.

Examination of the rectum should never be omitted in suspected cases. In those cases in which the diseased appendix hangs over the brim of the pelvis we almost always get rectal tenderness.

The author states that with one exception there has been marked leucocytosis in all the cases of perforation that have come under his care.

In regard to the treatment, the author believes that all cases of circumscribed abscess should be drained. The adhesions should not be broken between the abscess and the general peritoneal cavity. In a localized peritonitis of appendicular origin, where there is an adhesion to the abdominal wall, the incision should be made through the most prominent part of the tumor When the pus is reached, the abscess cavity should be drained by means of rubber tubing and gauze. If the cavity is very large and extends into the flank, flank drainage should also be used. The author thinks that drainage among the healthy intestines adds to the gravity of the case and for that reason is opposed to the tearing through of adhesions in cases of circumscribed abscess. Where it is possible to evacuate such cavities through the vagina the author believes that this is the best method to use. Nevertheless, drainage through the vagina and rectum is very unsatisfactory, and the author would not resort to this method unless the abscess was pointing unmistakably downward.

In the vast majority of cases the abdominal route must be selected on account of the abscess being unattached to the abdominal wall. Here every precaution must be taken to avoid contaminating the peritoneal cavity. The intestines should be protected by means of gauze and for this purpose the author prefers gauze sterilized by heat. Iodoform gauze he rejects on account of the dangers of absorption. In cases of localized peritonitis with probable general infection the adhesions about the appendix should be freed and the intestines thoroughly irrigated or wiped and every dependent portion carefully drained. Such cases should be operated on at the earliest possible moments, the earlier the better, just as soon as the gravity of the situation is realized.

In relapsing or recurring appendicitis the author believes that the operation should be advised and performed in all cases where, from frequent attacks, we are able to infer that there is chronic trouble. He thinks that it is a good plan to cauterize the base of the appendix before covering it in with peritoneum.

In regard to the use of the salines in appendicitis the author takes the ground that they may be given with safety in the majority of instances of catarrhal appendicitis, in appendicular colics, and even in slight extravasations not only in the outset but throughout the disease. Mild cases he to thinks do not require salines but do just as well on opium. There is always danger that a mild case will become a fulminating one and in the latter condition and in all cases marked by a sudden onset salines or other cathartics should be avoided. On account of the danger of causing extravasation he believes that cathartics should never be used in the beginning of an attack of appendicitis — that the use of opium is far more rational, if anything must be used. After the disease has been going on long enough to cause firm adhesions or after the appendix has been removed, or when, having drained a localized peritonitis, gauze barriers have been placed to prevent extravasation, it is a different matter and cathartics are useful. But up to four or five days the adhesions are not strong and the increased peristalsis may cause extravasation, and rupturing the adhesions produce a fatal peritonitis.

The author urges the importance of a through bacteriological examination and states that the bacillus coli communis has been found in most cases of septic serous effusions into the peritoneum.

In regard to the prognosis, he states that it depends entirely upon the variety. In the mild cases, with one or two exceptions, recovery without operation has taken place. The prognosis in cases of localized peritonitis is almost invariably good. Recovery has been invariable where the operation has been limited to simple evacuation, unless an incipient general peritonitis existed at the time. The prognosis where appendicular abscesses have been opened and drained is good. In case of well-established general peritonitis, where there is a severe constitutional infection, where the intestines are paralyzed by the local poison, the prognosis is invariably hopeless. Where there has been a serious attack of appendicitis, with an extensive localized peritonitis, or in those rare cases where recovery has followed a general peritonitis, a subsequent sudden perforation has been followed in several instances by the most rapidly fatal result.

Out of the 181 cases operated on there were 43 deaths—24.3 per cent. In practically all the fatal cases general peritonitis was the cause of death. One fatal result was due to delay in operating.

Dr. Charles L. Dana contributes a paper on

**The Microbic Origin of Chorea,**

reporting a case with the autopsy. As the results of his investigations the author believes that there is a meningitis of the cortex which extends into and in places involves the cortex. It is characterized by an active connective-tissue proliferation and the presence of diplococci in the meninges and cortex. In the meninges and cortex are small hyaline bodies which indicate a degenerative change of the brain substance. This degenerative change effects the deeper part of the brain to a less extent, extending down to into the capsule and lenticular nucleus, but not the optic thalamus. There is a meningitis with active vascular changes in the upper part of the cord which seems particularly to surround and effect the roots of the nerves as they leave the medulla and cord. The paper is illustrated by woodcuts of the patient and the microscopical appearance of a portion of the brain as well as a colored plate showing the hyaline bodies spoken of in the paper.

Dr. W. W. Keen reports

**Four Cases of Brain Tumor, in Three of Which Operation Was Done—Two Operative Recoveries—Ultimate Death in All.**

In the first case, the situation of the tumor was probably located correctly and trephining afforded a very great relief to most distressing symptoms. In the second, the tumor was almost exactly located, but, from the probable size and position of the tumor, and the condition of the patient, it was decided not to operate—a conclusion justified by the post-mortem. In the third, the position of the tumor was erroneously diagnosed, and an unwise operation was followed by death. In the fourth, the tumor was not recognized at the operation but was found at the suspected site at the post-mortem; the operation, while it could not afford relief, did no harm.

The author lays down the rule that tumors which are inoperable should be meddled with as little as possible. He also calls attention to the value of the amount of bulging of the brain as an indication of the size of the tumor, and which will, therefore, enable the surgeon to some extent to decide on the wisdom of greater or less interference in such cases.

The paper is illustrated by a portrait of one of the patients showing a peculiar bulging of the head after operation, and also the cuts of the brain showing the positions and size of the tumors. The paper will be continued in the next issue.

**Protozoa and Carcinoma.**

is the title of a paper by Dr. I. Adler. The author concludes his paper by saying that the existence of parasitic protozoa in cancer is probable, though the greater part of what has hitherto been described as parasitic is certainly not so. No constant or in any way specific organism has as yet been demonstrated beyond the possibilities of doubt. At present no facts, histological or otherwise, compel the assumption of a parasitic origin of carcinoma, while there are very strong and valid arguments against such assumption. Further study of the subject is urgently needed in the author's opinion.

The remaining papers in this issue are: "On the Neurosis following Enteric Fever known as "The Typhoid Spine," by Dr. William Osler; and "Some unusual New Growths of the Vulva," by Dr. R. W. Taylor.

---

THE CANADIAN PRACTITIONER

for December. Dr. B. E. McKenzie contributes a paper on

**Pott's Disease—its Early Diagnosis and Mechanical Treatment.**

He summarizes the teaching of the paper as follows:

(1) Due attention to the following symptoms and signs will generally enable the surgeon to make a diagnosis before the stage of deformity has come:

(*a*) The *clinical history*—noting the *chronicity* of the case.

(*b*) The peculiar *carriage* and *gait* in walking.

(*c*) Pain in the *distribution of the spinal nerves.*

(*d*) *Muscular spasm* in the region affected.

(*e*) Lateral or antero-posterior *curvature, other than that so called angular curvature which marks the later stage of the disease.*

(*f*) The *disposition to recumbency.*

(2) Mechanical treatment, permitting the patient to be out of bed, is preferred in most cases to plans which necessitate recumbency and a life indoors.

(3) The principles embodied in the use of the plaster jacket most fully meet the indications. When necessary to employ a head support, the croquet hoop is one of the best.

(4) Rawhide is a better material to employ than plaster of Paris.

(5) The object sought in immobilizing the spine is primarily to allay irritation and to lessen physiological activity in the part affected; and, secondarily, to prevent unnecessary deformity.

Dr. A. F. McKenzie discusses

**The Nature of Inflammation.**

He concludes that

(1.) It is a local process attended by structural, nutritional and functional changes in the part affected.

(2.) While these changes are locally injurious, and in the case of wounds hinder or prevent the normal healing process, yet they are probably an effort at defence on the part of the organism and the tissues affected.

(3.) While the most frequent essential cause of inflammation is probably a local invasion of pathogenic microbes, yet other causes may produce apparently the same effect.

(4.) Considering the desirability of not making any unnecessary changes in our terminology of disease, it does not appear that our knowledge is at present accurate enough to warrant us in limiting the term inflammation to the result of a local invasion of pathogenic microbes.

(5.) The antiseptic precautions which it is now considered necessary to take, and which, at least, are not apt to do any harm, are within the means and capabilities of ordinary practitioners, and he who is anxious to do the best he can for his patients will not likely neglect them.

Dr. T. K. Holmes reports "Two Cases of Laparotomy for Unusual Conditions." The first operation was performed for an ovarian abscess where the diseased condition was confined to the ovary, the fallopian tube being healthy. In the second case there was complete paralysis of the intestines requiring puncture of the gut to allow of the escape of gas. The patient recovered.

The remaining papers are "Mitral Stenosis," by Dr. G. A. Peters; "Rupture of the Heart," by Dr. J. L. G. McCarthy; and, in the clinical department the report of a case of "Cholecystotomy" with recovery, by Dr. J. W. F. Ross.

---

**An Infant with Alcoholic Liver.**

An inquest was lately held by the City of London Coroner on the body of an infant, aged six months, the daughter of a hawker. The mother deposed that she and her husband had tramped from Yarmouth to London, and that a doctor at the first-mentioned town had told witness to give the child some sherry and brandy, and so far as brandy was concerned, she had carried out his instructions. The medical man who made a post-mortem examination of the child deposed that the liver was four times the natural size, and that death was due to pneumonia. A verdict was returned in accordance with the medical evidence. A case of this kind is a forcible reminder that one cannot be too precise in giving directions to the uneducated friends of patients. Most persons familiar with the treatment of children's ailments know the value of brandy in emergencies. No sane practitioner, however, would order the prolonged use of alcoholic stimulants for children of tender age. The error probably lay in the failure of the Yarmouth doctor to impress on the mother that the spirit was to be used as a momentary stimulant only. —*Med. Press and Circular.*

## MEDICINE

### Treatment of Disease of the Appendix Vermiformis and its Results.

Drs. J O. Affleck and John Duncan recently read papers on disease of the appendix before the Edinburgh Medico-Chirurgical Society. Dr. Affleck said that within the last fifteen years it has been proven that the vast majority of cases of what was designated typhlitis and perityphlitis are due to lesions of the appendix. Inflammation of its substance is the disease to which it is specially liable. It would seem that the appendix may simply be enlarged and inflamed as the result of a catarrhal process, either extending from the cæcum, or set up by the presence of an irritating concretion. The changes in the appendix may be of more serious character, in the form of adhesions, torsions, suppurations, ulceration, perforation, and even gangrene. In such instances there is not only localized peritonitis, but not infrequently a collection of pus. He suggests that its peculiar vulnerability may be due to its being an unused structure, and consequently to its lacking the natural vitality of the rest of the alimentary canal. Dr. Duncan observed that we meet with three distinct varieties of the disease, the diffused, the localized, and the relapsing. In the first variety, the moment it is ascertained that the peritonitis is purulent, laparotomy must be performed. In the second variety, the guide to operation is the presence of pus. In the third, or relapsing variety, if the determination to operate be arrived at, it is well to do so in an interval of quiet, when the inflammatory action is least pronounced. In all cases of the acute variety in which the diagnosis may contain an element of doubt, as well as in all cases where purulent peritonitis is fairly assured, the proper course is to incise, in the first place in the middle line. In operating in that class of cases in which the inflammatory action is localized in the region of the cæcum, the situation of the incision will be determined by the indications of purulent collection, always with a tendency toward the point opposite the anterior superior spine, which experience has shown is most convenient for reaching the appendix.—*Edin. Med. Jour.*

### The Sort of Athletics for the Building of Strong Men.

Athletics have gained a strong hold upon college men (*American Lancet*). In fact, one hears more in the newspapers about Harvard's and Yale's athletic clubs than about their bright scholars. Many other colleges have won a certain notoriety by the success of their athletic clubs. A few years ago the writer knew a boy bright in scholarship, true in his manly instincts, noble in all his conduct. He was fond of athletics, and won distinction in Yale both as a scholar and as an athlete. But shortly after his graduation he was attacked with a fatal disease of the lungs. For his athletic work large lungs were needed, but when he dropped such work the lungs in their degeneration fell an easy prey to disease, and the world lost the services of one of the noblest of spirits. Not long since, on a visit to a college where students indulge in foot-ball, the writer observed that many had effusion into the knee-joint. He was told this was the "foot-ball knee." At least one example was observed in which this disease finally necessitated the amputation of the leg."

"Base-ball fingers" have become quite a common deformity—one which cripples in many ways in most pursuits of life.

No sort of athletics compensates for bodily deformities. Every physician is familiar with cases in which over-development of muscles in the training for certain games has resulted disastrously. Excessively developed muscles may be good for show, but they are not good for healthy life, especially in brain workers. Athletics for competitive feats of strength and endurance are pernicious, illogical, and dangerous (Lydston). It were far better for the average boy or man to be content with perfect control and excellent nutrition of muscles of moderate development. Strong men are not best constructed by the so-called perfect training.

Brain-workers and those who lead sedentary lives are unwise in attempting to become general athletes. That sort of athletics is best which (1) is free from serious danger to life and limb; (2) is natural and pleasing to the individual taking it; (3) promotes a healthful flow of blood through every portion of the body, the more equably the better; (4) is regular as is the hour for meals and sleep; (5) permits cheerful companionship; (6) does not seriously disturb thelordinary duties of life. In short, those ath etics are best for the student which are subordinated to his work as a student and the part he expects to take in after-life. Base-ball, foot-ball, lawn tennis, as friendly games for simple exercise, are well enough, but when entered into "to beat" they sadly lack the features needful to commend them to the thoughtful physician.—*Medical Review.*

### Anæmia of Miners in Children.

A grave form of anæmia is produced by the presence of a worm in the intestine, the Anchylostonum duodenale, first described by Dr. Dubini, of Milan. The author has been able to observe twenty-one cases in children below the age of eleven. Intestinal symptoms are more common than in other

forms of anæmia. The anæmia becomes rapidly worse. The fæces are very variable, often diarrhœic, sometimes streeked with blood; in other cases the stools are normal. The diagnosis is based entirely on the examination of the fæcal material, in which the eggs of the anchylostome are found. These are characteristic, being in segments—mono, bi-, poly-cellular. The eggs of the ascarides lumbricoides often accompany those of the anchylostome. The diseased arising in an infected locality (such as mines, collieries), the presences of other anæmics in the family, especially if among them were miners or men in similiar work, the resistance of the disease to different treatments, point to the diagnosis, and this is determined by the microscopical examination of the fæces. The treatment is by the ethereal extract of male-fern. The dose in children should not exceed four grammes, and should be given in an emulsion of some essence to conceal the disagreeable taste. It is necessary to repeat the treatment several times (four or five) at intervals of two to three days. As a contribution to the pathogeny of this form of anæmia, numerous experiments upon animals were made, which demonstrated very beautifully the anto-intoxication which takes place. After having prepared the toxine of the urine from two patients, after the method of Brieger-Otto, rabbits were inoculated with progressively increasing doses. The animals presented, from the first injections, all the characteristic symptoms of the anæmia in question. Quickly, upon stopping the injections, the animals returned to a state of health. Control experiments with urine of patients after the explusion of the worms, produced no changes in the blood of the rabbits experimented upon.—*Bost. Med. and Surg. Jour.*

---

**Frequency of Tuberculosis among Nurslings.**

The examinations of the author (Enguelne) were bacteriological and pathological, as well as clinical. They were made with great thoroughness, but were confined to the institution children of the Hospice des Enfants Assistes at St. Petersburg. These researches gave the following results:

1. Tubercle bacilli were found in fourteen out of one hundred and twenty children, i. e., 11.7 per cent.; bacilli existed in the lungs in ninety-three per cent., in the bronchial ganglia in ninety-three per cent., and in mesenteric ganglia in eighty-six per cent.

2. Thoracic tuberculosis was found alone in seven per cent of the cases, abdominal tuberculosis alone in seven per cent, and both together in ninety-three per cent.

3. The age of children dying of tuberculosis varied from two months and four days to seven months and seven days.

The author also tried to find the relation of tuberculosis to all the autopsies of ten years, as shown by the gross pathology, with the following result:

1. The mortality of tuberculosis varied from 0.82 per cent to 5.18 per cent of the whole number of autopsies, there being a mean of 2.62 per cent for the ten years.

3. Tuberculosis is most often first recognized between two and three months of age.

4. The increase and diminution of the number of cases of pulmonary inflammation, of intestinal catarrh, and of other affections bears a direct relation to the number of autopsies.—*Revue Mensuelle des Maladies de l'Enfance, Vratch*, 1892.

---

**Early Symptoms of Rheumatoid Arthritis.**

Mr. C. F. Griffiths contributes a paper on some neural phenomena of rheumatoid arthritis. The following are the phenomena to which he attaches the greatest importance. First, rapidity of pulse. Not in a solitary case, but in numerous instances, he has counted a pulse of 120, 130, 140, and even 160 to the minute; and yet the patient has been in all other respects non-pyrexial, and has not been subjected to any undue excitment, such as having just had a thermal bath, or exercise. Pigmentary cutaneous changes are of two very distinct forms—a diffuse melasmic discoloration, and a dark brown circumscribed spot, something like a mole, but not raised, and darker than the ordinary freckle. The next symptom is cold wet perspiration, notably of the hands, varying in degree from a mere clamminess to a profuse sweating, as if the hands had been dipped in water. This perspiration, however, is often found to be quite local, and it may be seen standing out upon the skin (especially the feet) following a defined course, as though influenced by one of the cutaneous nerves. There is often pain with this kind of perspiration; of a neuralgic character, and sometimes varying sensations of numbness and tingling. Fourthly, there is the true neural phenomenon of pain: not the pain which is associated with the disease-smitten joints, but that pain which occuring long before there is any evidence of arthritic trouble, Mr. Griffiths believes to be due to a perveted innervation of large nerve-plexuses, or a large area of nerve supply. This early pain occurs in the muscles of the thumb and inner side of the wrist, which suggests ulnar affection; ultimately the pain becomes more diffused and cannot be limited to any particular nerve area. This, especially when attended by the other phenomena, may, in most instances, be looked upon as the harbinger of the coming storm. Other neural symptoms are occasionally met with, such as loss of, or rather preverted sensibility of taste, interference with hearing, and severe gastric disturbances or migraine; and all these without any cause to account for them beyond the assumption that there lurks in the system a poison, of the exact nature of which we know little. As regards the respective values of these phenomena in the early diagnosis of chronic rheumatoid arthritis, that is, at a period before any arthritic or even constitutional symptoms have shown themselves, he thinks that the symptom of pain in localized areas is of very great importance and should be placed first; next, the increased

velocity of cardiac action; and then pigmentation. It will be readily assumed that should two or more of these symptoms appear synchronously or nearly so, the doubt would be pretty well turned into an almost absolute certainty.—*The Birmingham Med. Review.*

### Croupous Pneumonia in Children.

Dr. Francis Hawkins in a paper read before the Medical Society of London, based on 226 cases, says: Most cases occur during March, May and July; the fewest in January, August and December. They, occur, as a rule, independent of antecedent disease, and in the great majority the onset could not be attributed to any definate cause. Fifty of the cases occurred under the age of five years, one hundred and twenty between five and ten, and fifty between ten and fourteen. The disease was most frequent at the ages of five and nine respectively.

Connecting his table with a further series of over seven hundred cases compiled by others, he found that the frequency of the affection gradually rose from the fifth to the twentieth year. Its onset was usually sudden and its chief symptoms of invasion were vomiting, cough and pain, while rigors and convulsions were very infrequent, and hæmoptysis extremely rare. An arrangement of symptoms into groups showed that the nervous system was the one most variously affected. The average daily temperature before crisis was 103° and 104° F., and in about one-seventh of the cases, the fever was of the hectic type, though in only three was such associated with pus in the pleural cavity. The sixth was the commonest day of crisis, it being very frequent on the seventh and eight days. In basic pneumonia it was rather later than in apical. A dull tympanitic note was often present before any differentiation was detected in the character of the breath sounds. In one hundred and forty-six cases, the base of the lung was attacked in sixty-nine, the apex in forty-five; in the remainder the seat of the disease was in other parts. The most rapid respiration noted was 68. Typical rusty expectoration was present in seven cases, the youngest being six years old. Pleurisy coexisted in sixteen cases, pus being found in three. Gangrene of the lung occurred once. A soft systolic murmur was detected as arising during the course of the disease in six cases. Pericarditis was noted in one case, the patient having had rheumatic fever previously. Albuminuria was discovered during the disease in seven cases, and herpes in thirty-six, being in one case on the wrist as well as the angle of the mouth. Delirium was more frequent during the course of the disease than at the onset, and more in apical than basic cases. In the treatment, ice should be used with great caution when the pneumonia was on the left side, as the heart might become slowed and dangerous symptoms arise. As to alcohol, discretion was required to select the cases in which it was needed.—*Brit. Med. Jour.*

## ARMY AND NAVY.

U. S. ARMY, FROM DECEMBER 31, 1893, TO JANUARY 6, 1894.

First Lieutenant Edward L. Munson, Assistant Surgeon U. S. A., is relieved from duty at Jefferson Barracks, Missouri, and will report in person to the Commanding Officer, Fort Assinniboine, Montana, for duty at that post.

By direction of the Secretary of War leave of absence for two months, to take effect on or about January 15, 1894, with permission to apply for an extension of one month, is granted Major John D. Hall, Surgeon.

## NEWS AND MISCELLANY.

### Excursions to the National Capitol.

The Royal Blue Line has arranged a series of personally conducted three day tours from New York, Newark, Elizabeth, Trenton and Philadelphia to Washington, under the supervision of Thos. Cook & Son, the famous Tourist Agents. The dates selected are January 25, February 15, March 8, 29, April 19, 26, and May 10 and 17. The rate from New York, Newark and Elizabeth will be $13.00, from Trenton $12.25, and from Philadelphia $11.00, which will include transfers between depot and hotel and first-class hotel accommodations at Washington. The train will leave New York on above dates from station, foot of Liberty Street, 9.00 A. M., leave Newark, C. R. R. of N. J., 8.55 A. M., Elizabeth, Royal Blue Line, 9.31 A. M., Trenton, P. & R., 10.20 A. M., Philadelphia, 12th & Market Streets, 11.26 A. M., and 24th & Chestnut Streets, 11.42 A.M., and will arrive at Washington 3.00 P. M.

The tickets will be valid for the return journey on any Royal Blue Line train within three days, including first day of sale, thus affording tourists an opportunity to visit the public buildings and places of interest in and about the Capitol.

For more detailed information call on or write Thomas Cook & Son, 261, 1225 Broadway, New York, or 828 Chestnut Street, Philadelphia.

### ANTISEPTIC OBSTETRICS.

J. S. DUKATE, M. D., Pond Creek Mills, Ind.

The microbe reigns. In truth, its revels
In human woe, now beat the Devil's.
The greatest wonder, fear and dread
That now surrounds the child-birth bed;
Old doctors never dreamed it so,
When waiting on parturient ladies;
And if their getting up was slow,
The microbes didn't get the babies.
Carbolic acid, Listerine,
Were never thought of in those days,
Nor the Bichloride squirt-gun seen,
All primed to inundate the case.
The only exhortation given,
Was keep your bed, but change your linen.

Nearly fifty years in the practice of obstetrics and the management of 2400 cases of labor and after-treatment of the parturient women, in which number are included about all the varieties and complications of labor at full term besides numerous cases of abortion, ought, I think, entitle an experience and observation from a clinical standpoint, to some consideration in the department of obstetric medicine. Uterine, pelvic and peritoneal inflammations have been of a very small percentage following parturition, and that under what is now termed the "old fogy" regime in use before the present antiseptic parturium was in vogue.

It is proper that both sides of any great question should be heard, and all the facts collected, therefore, I offer a few thoughts on antiseptic midwifery as viewed to-day by so many eminent accouchers.

All admit that this is an age of culture and of scientific investigation, and that the medical profession is not behind in pushing onward and upward to the high place it is destined to occupy among the other sciences. But is there not danger in the struggle for pre-eminence among ourselves? Some are traveling so fast that they are found on some high eminence, way beyond the rank and file, watching for the whole army to overtake them. Wrapt up in their own conceptions, with microscope in hand, they stand making mouths at us, ignoring all the learning and clinical observations of the past, discarding *in toto* all etiology of diseases as taught by physiologists and pathologists of the past, and the ever present microbe, with them enters into every avenue of life and every tissue of the body—a specific bacillus for each human malady. *Wonderful Discovery!* In fact, our clothing, beds, carpets, food and drink are swarming with deadly bacteria, ever ready to pounce upon and annihilate us. But the horrid feature of this wonderful discovery is that the parturient woman is the one above all others, whose life is brought into jeopardy. This haunts the medical attendant day and night, and the entire *arcanum* of microbe-destroyers is brought into requisition to save her from an untimely grave. I admit all this savors of great learning; people stare and wonder, and one would think it was only by miracle or direct interposition of Divine Providence that our mothers survived the process of parturition if the present opinions relative to the management of the parturient female are correct.

If true, the larger number of women, especially in private practice, ought and necessarily would be the subjects of septicæmia, or toxic poisoning in some form, because of the absolute impracticability of carrying out the antiseptic precautions. But facts show such is not the case. I

have had patients placed under the most trying ordeal of poverty and filth, minus all the comforts of life, and yet these would do well, and that in the filth of their uterine secretions, no undergarments for a change, the very kind of soil to foster bacteria; yet these same women were soon up and attending to the duties of the housewife, having had no unfavorable symptoms. I acknowledge it makes us old physicians feel quite humble, and sometimes we almost feel that all our past reading and clinical observation is *nil*, when we see the young-fledged M. D. coming around with his weapons of offensive and defensive warfare against the supposed myriads of germs that threaten the citadel with destruction; but we apply the unction of "*vita brevis—arslonga.*"

Not long ago a physician said to me that he held he would be guilty of malpractice if before he made a vaginal examination in labor he failed to disinfect his hands, clean out his nails, and spray his person; yet this same physician has been engaged in an extensive obstetrical practice for thirty years and has not until recently paid any attention to antiseptic treatment in his midwifery practice. He has been a successful physician in this department to my certain knowledge, very few of his cases having been attacked with parturient inflammations. I requested an explanation for such a singular statement, and his reply was: "You had better be out of the profession than out of fashion." And he "did not propose to remain behind the practice of the day."

I believe the practice of the past for safety and a speedy convalescence from all forms of labor will compare favorably with the present notions and observances. If all is true that is claimed for the present practice, hundreds must necessarily be exposed from the absolute impossibility, under the circumstances, of methodically carrying out the practice. But then we have in cleanliness, soft water and good soap, with good ventilation, I opine, what will meet all the exigencies in about all the cases of parturition. Such has been my experience. A few years ago I was called in to see and treat the husband of a poor woman who a few days previously had given birth to a child. The season was one of oppressive heat. The stench from her undergarments and bed was intolerable from the decomposition of the lochial discharge, which was in excess, yet this woman had a good recovery. Every man who has been in practice a number of years has seen similar cases. Now according to modern opinions, this woman ought to have fallen a victim to some one of the puerperal maladies; but perhaps the bacteria if they did generate in such favorable soil were not so vicious and bloodthirsty as the bacilli of modern times. I repeat, pure air, good alimentation, water and soap are nature's antiseptics, and are about all any parturient female requires. In purely surgical practice, there is no doubt but antiseptics are of great utility, and are indispensably necessary; but there can be no question but what the same extremes have been reached as has taken place in relation to the best remedy in acute inflammation, when judiciously and scientifically employed, viz., blood letting. Common sense and conservatism in medicine is the safe rule; it is the only rational one. The notion that every ill which befalls the parturient female is produced by a specific microbe, and calls for a routine of an unnecessary and often impracticable line of management, which results more to the enhancement of her medical adviser in the opinion of his patient than it does for her protection and comfort, is more, I opine, a fashion in modern medicine than a reality.

I cannot divorce myself from the opinions of the past in regard to the etiology of diseases, especially those which are characterized by acute inflammation—puerperal peritonitis as an example. That the greatest number of the phlogistic maladies are produced histogenically or autogenically, I think is beyond cavil; the peculiar *materies-morbi* so acting upon the blood as to result in acute inflammation. Then, again, meteorologically considered, the direct or remote effects of cold are all factors in the etiology of disease. Several cases of puerperal fever have come under my observation that could be traced to the direct influence of cold upon the system.

Fearful epidemics of puerperal fever prevailed in Edinburgh in 1793, and in Paris, Vienna and Aberdeen in 1795. These epidemics were written up by such clinicians and pathologists as Lock, Hunter, Clark, Campbell, Tonille, Armstrong, Meekell, Lee, Collins, Furguson, Dance, Bovine, Duges and Gordon and Columbat. These authors, all of whom were actively engaged in the treatment of

this fearful epidemic, both in hospitals and private practice, all speak of and describe a peculiar condition of the atmosphere that unquestionably prevailed and gave rise and continuance to the epidemic.

I think the judicious and unprejudiced physician will not adopt in haste and unreservedly any of the leading doctrines advanced in modern medicine. Looking back over the literature and clinical experiences of the past, he will still see a great deal to admire and embrace in the systems of Brown, of Cullen, of Darwin, of Broussais, and even of the fanciful Hahnemann; although when offered to his acceptance as doctrines of universal application, he may very reasonably refuse his assent.

The advocates of bacteriology endeavor to support the doctrine with the microscope and by culture; by the phenomena of post-mortem examination, and by arguments founded on physiological principles. It is affirmed that bacteria are present in this and that disease, therefore, the bacteria must necessarilly be the factor in the etiology of the disease, and are responsible for all the morbid changes. Now parasite conditions may be the result of previously existing morbid conditions, therefore, the mere presence of any variation from the normal is no proof that this condition was the primary cause of the disease in question, but it is in all probability only the result of pre-existing morbid action. Admitting that such manifestations are as universal as they are asserted to be, is there not much reason to believe that very frequently, at least, this very condition supervened during the course of the disease as a consequence, rather than that pathological conditions having been pre-established, and become the immediate cause of so many febrile and inflammatory diseases. We frequently see inflammation supervene in parts exposed to observation many days after general fever has been fully established, why not then other products devoid of organizable lymph and pus cells—the result of morbid changes going on in the diseased parts, yet not absolutely known to the searching investigation and reasoning powers of the pathologist. The theory is as yet a *vexata questio*.

QUERY—If parturient females are in so great danger, why does it not bring all women alike subject to the baneful influence of this dangerous microbe, or is it alone confined to the civilized and cultured? The Greenlanders mostly do all their common business just before and after their delivery, and a peritoneal inflammation is seldom heard of. Long tells us that the Chippewa women as soon as their child is born go into the water and immerse it saying "Oway saggonosh payshik shomagonith," or "here is a young warrior."

Lempriere says: "Women in Morocco suffer but little inconvenience from child bearing."

"The Shangalla women bring forth children with the utmost ease, and never rest or confine themselves after delivery."

Immediately after delivery of the placenta, all clots should be removed from the vagina, and an agreeable bandage applied; all saturated clothing removed; the room kept well ventilated; a light yet nutritious diet allowed, and perfect rest in the recumbent posture enjoined. Then follows a discharge of a sanguinous fluid from the uterus for a few days, which becomes greenish, and lastly pale, and decreases in quantity, disappearing altogether within a month, and often in a shorter time. This is called the lochial discharge. During this flow it is only necessary that the vagina and external parts be daily washed with tepid milk and water. Constipation should be avoided; and the condition of the lacteal secretion looked after. The above is under all ordinary circumstances about all that is necessary for the medical advisor to do for his patient, and the above strictly enforced will, as a rule of conducts, be all that any woman will require for the successful recovery from parturition.

In conclusion, should this article fall into the hands of the older members of the profession who are competent to judge, it will, if faulty do little harm; but should it fall into the hands of the student of midwifery, it will prove useful or injurious to society, according to the correctness of the principles it contains. When I consider how important the diseases of women are, especially of the parturient woman, and how important the prudent management of labor and the entire puerperal state, I think I comprehend the responsibility which falls on those who presume to practice this art. And I feel that what I have stated as my honest conviction, will be found to agree with the observation and experience of our best teachers and practitioners of obstetrics.

# COMMUNICATIONS.

## SURGICAL SHOCK.*

CHARLES P. NOBLE, M. D.,† PHILADELPHIA.

It is proposed in this communication to briefly consider the nature of surgical shock, and then to take up its treatment in detail. Shock is a condition of the body which is characterized by feebleness and rapidity of action of the heart, by the shallowness and frequency of respiration, by the lowering of the temperature of the body, and by the lessened activity of most of its functions. Intellection, digestion, and the secretion of urine all are more or less in abeyance. It is probable, also, that the processes of assimilation and metabolism are profoundly interfered with. Perspiration is usually free, the body being covered with a cold, clammy sweat. This, however, is due not to the increased activity of the sweat glands, but rather to an arrest of the activity of their cells, so that they simply act as strainers for the watery part of the blood to pass through them.

There can be no question that vitality is at a low ebb when shock exists, but there is some difference of opinion as to the real physiology or pathology involved. It is generally accepted that shock is a manifestion of paresis of the nervous system, its symptoms being due to lessened and irregular innervation. The question as to whether the cerebro-spinal or the sympathetic system is most involved is in dispute, and we do not propose at this time to attempt the elucidation of the question. As a matter of fact, injury of the body in any of its parts can bring about shock. Injury to certain parts of the body are especially liable to produce shock. These parts are the testicle and urethra, in the male, the ovary (in a lessened degree) in the female, and the abdominal viscera. Examples of shock from injury to these structures are common, and familiar to every one of experience. The familiar experiment of temporarily arresting the heart's action of the frog by a blow upon the abdomen is a striking illustration. Leaving aside the disputed points at issue, we wish to consider certain facts because of their very practical bearing upon the therapeutics of surgical shock. Among the most important symptoms of shock is the lessened force and greater frequency of the heart's beat. The activity of the respiratory centre, also, is much lessened. The superficial blood-vessels are contracted, so that the surface of the body is pale and even blanched. The temperature of the body is lowered below the normal. These facts are indisputable, and a recognition of the existence of these conditions forms the basis for rational therapeutics. Heat must be restored to the body; the heart and respiratory centres must be stimulated to do their work; and the superficial blood-vessels must be dilated, so that the circulation may be equalized by affording a channel for the blood which has been retained in the great veins of the abdomen. The practice which I followed for some years to accomplish these results will now be given.

*Treatment of Shock.*—The most important point in the treatment of shock is its prevention. Much can be done by prudent management, either to avoid shock or to lessen its degree. In selecting the date for operation a time should be chosen when the patient is in good condition. Almost always this is possible. It is only in emergency cases, and in patients who are suffering from a disease whose progress is steadily and rapidly downward, that preparatory treatment will not put them in better condition. All patients requiring operation should receive careful study, and every therapeutic indication should be met before operation. Especially should the condition of the emunctories be looked after. The bowels, skin and kidneys should be put in good condition by the use of baths, purgatives (especially broken doses of calomel and salines), and the abundant ingestion of water. The *morale* of the patient should

*Read before the Obstetrical Society of Philadelphia, December 7, 1893.

† Surgeon-in-Chief of the Kensington Hospital for Women

not be neglected, as much can be done, by stimulating the courage of the timid and allaying the fears of the despondent, to make the patient look forward to the operation with courage and without dread. All these matters should be attended to prior to the day of operation. The temperature of the room in which the operation is done should be high, from 75° to 85° F. In such a room the loss of heat from the patient by radiation is much less when the operation is done in a cool room. Loss of heat from the patient can be lessened also by the manner in which she is dressed. It is best that she be well wrapped in blankets, and that as little of the skin surface be exposed to the air as the necessities of the particular operation permit. For the same reason the use of wet towels or gauze about the patient is to be deprecated .Evaporation from such wet material chills the patient. Much can be done also by the proper administration of the anæsthetic. Patients should not be drowned in ether. Enough only should be given to maintain anæsthesia, unless to meet a certain indication, absolute relaxation is required. The prevention of hemorrhage, and the avoidance of rough handling of the patient, especially of the abdominal viscera, are matters of the greatest importance in preventing shock. The careful surgeon gives due attention to each and all of these matters of detail, and no one so much appreciates their importance as he who has to deal constantly with grave operations. This applies especially to the abdominal surgeon, because in many cases, when he begins an operation the life of the patient depends upon its completion. He cannot do a part of it and postpone the rest to another day. In many of the long, tedious operations which he is called upon to do, involving multiple visceral adhesions, the very life of the patient itself depends upon attention to every detail to prevent shock, so that he may have time to complete the operation *secundem artem*.

The active treatment of shock consists in supplying heat to the body which has been lost, in stimulating the heart to better work, in counteracting nervous depression, and in overcoming irregular action, especially on the part of the vasomotor nervous system, until reaction shall occur and the vitality of the patient can be sustained by alimentation. In describing the treatment of shock I shall simply give an account of my own practice in the treatment of this condition.

If during the operation the patient begins to suffer from shock and here is reason to expect that this will increase, especially when the operation is not yet completed, I begin at once actively to treat it. One-fifteenth of a grain of sulphate of strychnia and one-fiftieth of digitalin is given hypodermically, and the dose of strychnia is repeated every fifteen minutes until some improvement is manifested in the pulse, until a fifth of a grain is given. If improvement does not manifest itself promptly, and especially if shock be profound or if the patient has been markedly prostrated before the operation, a hundredth of a grain of atrophia sulphate and two or three minims of a 1 per cent. aqueous solution of nitroglycerine are given hypodermically. In still other cases from three to six grains of citrate of caffein are administered in addition. During this time hot-water bottles have been put about the patient, and if the operation is an abdominal section, at times warm water is poured into the peritoneal cavity. I have also employed hot beef-tea enemas, but, as a rule, an enema is not given, because it interfers with the completion of the operation, which is just as important as any one detail in the treatment of shock if not more so. In fact, it is of the highest importance to complete the operation as rapidly as is consistent with safe work. The same is true of the after-dressing of the patient, who should be put to bed as promptly as is feasible.

The bed should have been warmed by having hot-water bottles in it while the operation was in progress, and in all cases in which shock is a marked feature, the sheets should be removed and the patient placed between warm, dry blankets. At this stage the use of whiskey by enema is of service, and at times it is proper to use whiskey during the operation, especially if shock is not another name for too much ether. The use of whiskey or alcohol in any shape is not good treatment for an overdose of ether. The best way to employ whiskey, as a rule, is to give it by enema with hot beef-tea, about two ounces of whiskey and six ounces of beef-tea. Dry friction with the hand or with a dry cloth, especially to the extremities if they are covered with clammy perspira-

tion, will do much to bring about reaction, and also will lessen radiation from the surface by preventing evaporation of the perspiration. Morphia in small doses, one-eighth of a grain or less, is also useful as a heart stimulant and as a an anodyne, if, when the patient becomes conscious there is marked pain. The morphia not only acts as a stimulant itself, but prevents depression which would result from severe suffering. So much for the immediate treatment of shock. Under ordinary circumstances, when the shock is marked and yet not so profound as to be alarming, within half an hour strychnia can be pushed to a fifth of a grain, atrophia to a fiftieth, caffein to five grains or more, and digitalis to a twenty-fifth of a grain, or what is really better, tincture of digitalis to half a drachm, with the fiftieth of a grain of nitroglycerine.

If the crisis passes and yet the patient remains in a markedly depressed state, the question of treatment for the ensuing twenty-four or forty-eight hours comes up. The use of external heat should be continued until the temperature of the body becomes normal, and even longer should the patient complain of chilliness. But the sheet anchors of safety are strychnia, digitalis and whiskey. In a marked case it is my habit to give the following order: To give hypodermically sulphate of strychnia, one-thirtieth of a grain one hour; tincture of digitalis, fifteen drops, with the one-fiftieth of a grain of nitroglycerine, the next hour; three grains of citrate of caffein the third hour; and an anema of whiskey, two ounces, and beef-tea, six ounces, the fourth hour. This order I have had carried out many times for twenty-four, forty-eight and even seventy-two hours. In the worst of cases, for its temporary effect, cocaine has been employed in addition to the above, also small doses of morphia if much pain and especially if great restlessness were present. It is my experience that most patients will take a fifth of a grain of strychnia in twenty-four hours without manifesting symptoms of strychnism. I have not employed the heroic doses of strychnia described by some writers, such as half a grain within two hours, but in a desperate case, watching it carefully, I should not hesitate to give repeated doses of one-fifteenth of a grain every half hour for a short time until some symptoms of irritation appeared. We certainly have no more reliable exciter of the nervous and muscular systems than strychnia, nor any drug which is more capable of maintaining its effect.

Digitalis is also a very reliable drug in the treatment of shock. It is capable of whipping up the heart to increased work, especially for a few days and until a sustained effect can be secured by alimentation. This is exactly what is required in the treatment of shock. Digitalis has, however, one effect which is undesirable. It causes a contraction of the arterioles, and thus increases arterial pressure, so that while it whips up the heart to do increased work, it also hinders the heart through the increase in arterial pressure; hence, it is wise in the treatment of shock, to combine digitalis with nitro-glycerine, which overcomes this bad effect of digitalis. The combination is much more effective than either drug alone. Caffein is a pure heart stimulant, and can be administered freely without evil consequences. Alcohol used judiciously and in not too large quantities, is one of our most important remedies. In shock following abdominal operations, it is best administered by enema combined with beef-tea, which is itself a stimulant. Later in the case champagne by the mouth is often of service, but it fills only a partial indication and is not to be compared in value with whiskey when this can be ingested and retained.

The management of the diet in the treatment of shock is also important. Immediately after an operation accompanied by much shock, the stomach, as a rule, is not retentive; hence it is wise for a time in no case to administer much aliment of any description by mouth. Some hot black coffee or hot beef-tea is as much as should be given. When the stomach becomes retentive, light, easily assimilable food should be employed, as beef-tea, broth, milk (preferably peptonized), egg-nog, punch, etc. These foods should be administered in small quantities frequently repeated. The question of alimentation in the treatment of shock following abdominal operations offers certain peculiar difficulties. Under ordinary circumstances, when shock is not a special feature, it is the rule to administer no food to the patient, who has had a

cœliotomy, for from thirty-six to forty-eight hours after the operation. Then broths or beef-tea from two drachms to one ounce, or two drachms of milk with one of lime water, are given every half hour, and if retained the quantities are increased and the intervals lengthened, until about the fourth day after operation the patient is put upon liquid diet, the amount being regulated largely by the appetite. But in cases accompanied by marked shock, if the stomach proves retentive, it is wise to begin the administration of milk or beef-tea at the earliest feasible time, the quantity being increased as rapidly as in the judgment of the surgeon the patient is able to digest and to assimilate. In some critical cases lives will be saved by judicious alimentation, which would be lost were the usual rules, applicable in abdominal surgery, followed.

It may be questioned whether the term shock should be applied to conditions which persist for one, two, three or more days. It is customary to consider that shock is of temporary duration, and that it ends either in the prompt death or in the recovery of the patient. But there are cases in which it is difficult to assign a name for the condition of patients, if it be not shock. I refer to those cases in which the patient exhibits marked shock after operation, and in which, although after a time the temperature of the body becomes normal and remains so, yet the patient's vitality remains at a very low ebb, the pulse continues rapid, small and feeble. The cutaneous circulation is not restored, the surface of the body being cool and pale; and where no other symptoms are present, except those of pronounced asthænia. This condition must be called shock, or else inanition or asthænia following shock. The condition persists until it is relieved by alimentation, as the nerve and heart stimulants, strychnia, digitalis and even whiskey, are not curative. I have had patients to die in this condition as long as a week after operation, without having manifested other symptoms than those of pure asthænia, and in which the post-mortem examination showed no cause of death. On the other hand, I have seen patients recover from this condition, improvement becoming manifested upon the third, fourth or fifth day, when it had appeared that death was imminent from failure of the heart and respiratory centres. It is in such cases that judicious alimentation is of the highest importance.

In this class of cases the administration of oxygen gas by inhalation, is at times of service. All the vital functions are at such a low ebb, that any agent which is capable of improving the processes of metabolism is of value. My experience with the use of oxygen for this purpose is limited to one case; which was one of marked shock following an operation for double pus tubes, in a woman reduced to the last extremity by hectic. She went to bed with a pulse of 180, with cool and blue skin, and every other evidence of the profoundest shock. The pulse did not fall below 145 for three days, near the close of which period there was every indication of early death from pure asthænia. The plan of treatment already detailed was followed out in her case, and in addition oxygen gas was administered during one day. It seemed to be of great benefit; at all events, she passed out of the shadow of death and made a good recovery.

### Higher Medical Education.

"In pursuance of the policy recently announced in the resolution to be presented to the American Medical College Association, the trustees and faculty of Rush College have decided to require four years' attendance at College from students who began the study of medicine this year with a view to graduation in 1898; however, those who have already studied medicine one year or more witht a preceptor so that the four years of study, already acquired will be completed before July, 1897, may graduate after three courses of lectures as heretofore. To encourage proper preliminary study, graduates in Arts and Sciences from high-grade colleges, and graduates in Pharmacy and Dentistry from colleges requiring a proper amount of study, and two full courses of lectures will, until further notice, be allowed to graduate after an attendance on only three courses of lectures."

ONE HYPOTHESIS.—She.—"Why is it when physicians get sick they never attend to their own cases?"

He.—"I don't know, but I should say it was because they can't charge themselves anything for it."—*Life.*

## OCCLUSION OF THE OS UTERI COMPLICATING LABOR AT TERM; ABDOMINAL PREGNANCY.

P. L. HILLSMAN, M. D. ALBANY, GA.

Mrs. H., aged 29; robust, well developed; married nine years. Began menstruating in her 14th year, and was quite regular until she conceived. Six months prior to conception had some form of uterine disorder, and was under the care of a physician until a short time before she missed her menses.

Gestation progressed without any unusual symptoms to full term labor; pains commenced about 1 A. M., and continued until 7 A. M., when I was called to attend her. On arrival I found the pains frequent and rather of an expulsive character. Digital exploration revealed uterus well descended into pelvic canal, with the ovoid form of a vertex presentation, but no os could be found.

After a more minute examination I detected a point somewhat depressed and more attenuated than the surrounding tissue, and being satisfied that it was the os occluded by adhesive inflammation, I proceeded to operate as follows: An ordinary uterine sound was forced through the most depressed point, this was followed by a uterine dilator, and parts expanded until the index finger could pass. Full dilatation was now gradually accomplished with the fingers, aided by moderate chloroform narcosis, and labor terminated without further assistance at 5 P. M. Child was still born, attributable to tedious and prolonged labor. Patient made an uninterrupted recovery, and has since been perfectly regular in her menses.

*Remarks.* The history of this case goes to show that at the time of conception she had endocervicitis, which resulted in adhesion of the parts, there being no menstrual flow to mechanically expand the os.

---

M. J., colored; age 42; married; has given birth to five children—last child four years ago; consulted me April 1, 1892, with a history as follows:—Fifteen months ago missed her menses, symptoms of pregnancy followed. She also thought that she experienced quickening, and made ready for the event of parturition. Having gone several months over her time without any symptoms of labor, she consulted a physician, who informed her that she had uterine fibroid, and that she would in all probability get relief after her courses left her. She was comparatively well at the time and continued her vocation—that of an ordinary hand in the field—until about one month before consulting me, when, owing to feeble health, she was compelled to give up her work. The patient, at the time of her visit, was emaciated; complained of gastric disturbance said that she felt as if her stomach was not large enough to hold sufficient food to satisfy her hunger, and vomiting ensued if a moderate meal was taken. Abdomen enlarged, presenting the appearance, of pregnancy at term. On examination I found the uterus anteverted, and with difficulty passed a curved sound three and one-half inches. The tumor gave some evidence of semi-fluctuation. Case was diagnosed as ovarian cyst, possibly malignant in character, as patient had lost flesh rapidly, and the gastic disorder led me to suspect similar trouble in stomach. Operation urged, but owing to her husband being actively engaged in crop, it was deferred for the time. The patient was placed on a tonic course, and nutritive diet ordered in small quantities and often repeated.

July 1st, patient returned and insisted on the operation; stated that she had gained some strength shortly after first visit; had her menses to come on twice, and was hopeful of recovery, but for the past two weeks had begun to fail again, and vomit to her food. Operation July 4, 1892. Under strict antisepsis, abdominal incision was made from the umbilicus down near to symphysis; walls very attenuated and completely adherent to sac. After freeing adhesions on the left side, about one inch from median line a peculiar pouch was discovered, which was at first very puzzling. On further dissection, however, it was found to be a reflection or folding of the sac on itself. This was caused by a partial absorption of the liquid contents of the sac, and the resilient abdominal muscles caused an overlapping of the flaccid walls. The sac having been freed as far as the incision

would allow, a trocar was introduced and the liquid contents withdrawn. Only about one pint of thick caseous matter passed, the appearance of which rather strengthened my fear of malignancy.

Finding it impossible to bring the mass through this opening, the incision was enlarged through and above the umbilicus about four inches. Further effort was now made to free the sac from its intimate adhesions to the adjoining viscera, which being found impracticable was abandoned. The sac was now incised and to my great relief was found to contain a well preserved child weighing seven pounds. This with its shriveled placenta was readily extracted without any hemorrhage. The free portion of the sac was removed and the edges stitched to the abdominal walls. A drainage tube was placed in the abdominal cavity at the lower point of incision and the sac loosely packed with iodoform gauze. Dressing was completed with a thick wadding of iodoform cotton, covered by gauze and bandage.

The patient rallied well from the operation and began to cry piteously for food. She was allowed one teaspoonful of Wyeth's meat juice every four hours, and small quantities of crushed ice.

July 5th—Temperature 99½° F. Slept well during the night from hypodermic of morphia. Still clamoring for solid food.

July 6th—Temperature 100½°. Allowed milk with lime water, in small quantities, and egg albumin water.

July 7th—10 A. M., found patient in collapsed state, with great pain in the bowels; abdomen much distended with flatus, more particularly over region of stomach. Breath exhaled an odor of decayed eggs. On questioning the attendant, her husband, he acknowledged that he had given her three eggs for supper on the previous night, and other things in proportion. He said he did not think she would ever get up without getting more to eat. A stomach tube was inserted and about half a gallon of offensive matter removed and the organ cleansed with warm water. Dressing was removed and the wound found in good condition; very little discharge having taken place since operation. The patient did not rally from the collapse, and died at 6 P. M. Her body was removed the same night to the country and consequently no autopsy was made.

*Remarks.*—The progress of this case up to the third day, led me to hope for a favorable result, and the unhappy termination should justly be attributed to the pain and distress incident to the heavy meal of eggs, etc. The condition of the wound would exclude septic poisoning as a possible cause of death.

## A VERY UNUSUAL FOREIGN BODY IN THE LARYNX.*

W. H. Newman, M. D.

On December 23rd, I. E., an infant ten months old, was presented at the office with the information that at noon of the 19th, she had swallowed something which "stuck in her throat."

The father was under the impression that the offending body was a part of a hickory nut. The child had no symptoms except a slight difficulty in deglutition—could nurse easily, and was as full of life and playfulness as ever.

Another physician, consulted the day previous, said that he could detect the nut, but could not extract it.

When the child ceased crying, Dr. Clark auscultated the thorax and detected an abnormal whistling sound in the larynx, which was so unusual as to favor nothing but a foreign body. Introducing the finger into the oro-pharynx, and raising the epiglottis, an abnormality was at once felt. After several attempts to loosen the body with the finger, a pair of small dressing forceps were inserted and the body extracted. This was nothing less than an open safety pin. It was evidently astride the rim of the glottis, the pin part projecting into the œsophagus, and the fastener in the larynx. This accountsfors the fact that it passed neither into the trachea nor the stomach, and that it w a not coughed up, the arm of the fastener preventing.

The points of interest in the case are:

1st. The rarity of the accident.

2nd. The paucity of subjective symptoms.

3rd. The difficulty of diagnosis and treatment in a struggling infant.

4th. The value of perseverance in such cases.

* In the practice of E. Clark, M. D., Grinnell, Iowa.

# SUBCUTANEOUS INFUSION OF A NUTRITIVE SALT SOLUTION IN CASES OF REFUSAL OR INABILITY TO TAKE FOOD.*

MILTON D. NORRIS, M. D.†

Although the intra-venous and subcutaneous injection of large quantities of fluid, for the purpose of keeping up the blood pressure, has long been practiced, I believe the idea of administering nutriment by subcutaneous infusion originated with Dr. George H. Rohé and was first used in this hospital.

Ilberg and Lehman in Germany, within the last year, report several cases in which good results followed the hypodermic injection of 600 cubic centimeters of a saline solution in the fasting insane, but these gentlemen used a simple salt solution without any actual nutriment.

In the cases I am about to report, the solution used was composed of twelve to fourteen ounces of sterilized water, to which, after partially cooling, was added the whites of two eggs and thirty grains of common salt. This was filtered through cheese cloth. The resulting liquid had about the appearance and consistency of simple syrup, and would coagulate on being heated. Only the whites of eggs were used, because they do not require any previous digestion, but can be directly assimilated.

An ordinary stomach tube and a medium-sized aspirating needle were the only instruments employed in giving the infusion. No force, except that of gravity, was used, and generally only one puncture of the needle was required. The loose tissue over the gluteal region was always selected as the point of puncture, and the time required to inject the fourteen ounces was never over fifteen minutes. The injection of this large quantity of fluid in such a limited area would, of course, make a considerable swelling; but this would disappear in an hour, and there was not a single case in which any bad effect followed the injection.

The subcutaneous method has the advantage over the intravenous of a gradual absorption of the fluid, and therefore no danger of overwhelming the heart, besides there is no danger of emboli or the admission of air into the veins; and this method can be used by any one with a little care, while the intra-venous can only be used by the skillful.

The first case was M. J. K., male, aged fifty years. Case of chronic mania, who was constantly dirty, noisy and tearing. He had been fed for some time by means of the stomach tube, but became weakened and more emaciated every day. He was given fourteen ounces of the fluid at intervals of four days, and fed on the intervening days. His appearance and condition greatly improved, and on the day after the third infusion he began to eat and has given no trouble since.

Case 2. W. P., male, aged sixty-five years. Case of dementia, suffering from Bright's disease. At time of admission his pulse was sixty-four, and every attempt to swallow was followed by vomiting. All efforts to feed by the mouth were stopped and he was given the infusion every day for four days, at the end of which time there was marked improvement; his pulse being eighty and much stronger. He was then able to retain food on his stomach, but from time to time had attacks of vomiting and after several months again became so weak that the infusion was repeated with good results.

Case 3. T. C., male, aged eighteen years. Case of acute mania. Admitted January 24, 1893, at which time he was constantly swearing, crying or singing, and biting at every one who came near him. He was in a very weak and emaciated condition, owing to his refusal to eat for several days previously, and was fed the usual quantity of milk and eggs by means of the stomach tube, but soon vomited all he had taken, and during the next twenty-four hours was not able to keep anything on his stomach, although several attempts were made. All efforts to give food by the mouth were stopped, and fourteen ounces of the infusion given daily for three days, during which time he received no other nourishment. On the fourth day he was much stronger and perfectly quiet, pulse good, tongue clean, and complained of being hungry. He was given food, which was retained, and he ate regularly with a good appetite afterwards. This

* Read at the semi-annual meeting of the Med. and Chirurg. Faculty of Maryland, November, 1893.

† Ass't Physician Maryland Hospital for the Insane.

patient has since been discharged from the hospital cured, but I believe he would have died from exhaustion if the infusion had not been used.

CASE 4. A. E. C., white, female, aged fifty-two years, case of acute mania. Patient was very violent, and was fed with a stomach tube, but this had to be abandoned on account of an abscess involving the mouth and throat. She was given the infusion on three successive days, but died on the fourth day from exhaustion caused by the extensive inflammation of mouth and throat.

CASE 5. E. D., white, female, aged forty-eight years, case of epileptic insanity. The epileptic seizures occur once in two or three months, and are followed by a period of depression. During one of these depressed periods she refused all food for several days, and was given the infusion on three successive days. She improved considerably and began to eat on the fourth day.

CASE 6. R. L. T., white, male, aged thirty-one years, case of simple melancholia. This patient refused to eat, and despite persistent feeding with duck and stomach tube he became weaker and took to bed in a very weak and emaciated condition. His secretions were foul and vomiting occurred frequently. The infusion was given on four successive mornings, and although during this time, over 100 hours, he did not take any food into his stomach. His condition in every respect was better than it was before receiving the infusion; his tongue became moist and clean, pulse stronger, and his mental condition was much better. He asked for food, and has so much improved that he now has liberty of the grounds, and will most likely be sent home in a short time. This patient was discharged recovered, November 19, 1893.

It is well known to every alienist that certain cases of melancholia with refusal of food, not due to illusions will gradually emaciate and die in spite of the most persistent artificial feeding, and it is in these cases that the subcutaneous infusion of nourishment will find its greatest use.

In cases of delirium tremens where the stomach will not tolerate anything, this method affords an excellent means of keeping up the patient's strength during the three or four days that the stomach is resting; also in severe cases of vomiting of pregnancy, and any case where the stomach must have rest, this method of giving nourishment will be useful.

It has the advantage over rectal feeding of not being so dangerous or so disagreeable to the patient, and of being more certain in its effects, besides it stimulates the heart, and increases arterial tension which is important in cases that are very low, as most of these will be in which this method is indicated.

I believe this method of administering nourishment can be used to advantage in a considerable number of cases by both the alienist and the general practitioner.

---

**A Fours Year's Course at Jefferson Medical College.**

At a meeting of the Faculty of Jefferson Medical College, held on January 8, 1894, it was unanimously resolved to institute a compulsory four years' course with the sessions of 1895–'96.

This step was taken in order that the large clinical service of this Jefferson College Hospital (350 cases a day) might be utilized to the fullest extent in carrying out the desire of the faculty to provide advanced Medical education of a practical character.

IT IS reported that there are 700 women practicing medicine in the Russian Empire, and a new school of medicine for women has just been started in St. Petersburg, with a four years' course of study. To the support of this school the State contributes annually 15,000 rubles, and from one to three years' service in the hospitals for women and children is expected of the students before they present themselves for the final examination.—*Pub. Opinion.*

## SOME AFFECTIONS OF THE EXTERNAL AUDITORY CANAL.*

S. G. DABNEY, Louisville, Ky.

[CONDENSED.]

The most common affection of this part of the ear is accumulation and impaction of the ear wax. Frequent as this symptom is, we are yet often unable to attribute it to any definite cause. It may be due either to over activity of the ceruminous glands or to a dermatitis of the canal which prevents the passing outward of the wax as usually occurs.

Burnett has observed that persons whose sweat glands are very active are likely to be annoyed by impacted cerumen, and it has been my observation that these cases occur more often in warm than in cold seasons. Whether this is due to over-formation of wax or to its being softened and running down on the drum membrane, is open to question; but the resemblance in structure between the sweat and the ceruminous glands gives color to Burnett's suggestion, that their activity may be excited by the same cause.

An accumulation of wax is more often produced by over-zealous efforts at cleanliness than by neglect. The habit of pushing into the ear a little of the twisted end of a towel or the use of instruments of any kind in the patient's hands is much more likely to push any wax that is present further in than to remove it. The symptoms of impacted wax are so familiar as not to require mention. They are most often of sudden occurrence and very frequently are first observed after a bath, by which the wax has been so carried down as to press on the drum membrane. In such cases patient's are in the habit of saying that they have gotten water in the ear and could not get it out. It will be observed that the symptoms produced by impacted wax depend largely on the position; so long as it is loose in the canal, a considerable quantity may remain unperceived, but when pressure is made on the membrana tympani symptoms are often very annoying and may indeed be serious. A case was reported where the patient thought his ears had been effected by a stroke of lightning. An examination revealed resting against the drum membrane a mass of wax, the removal of which gave entire relief to all the symptoms.

In a certain proportion of cases the condition of the ceruminous glands seems indicative of disease of the tympanum. This is best marked in the so-called proliferous or in advanced catarrhal inflammation; in such cases there seems to be atrophy of the sweat glands and patients often volunteer the statements that their ears are dry and secrete no wax. In early catarrhal disease either of the naso-pharynx or middle ear, there is said to be an over-production of cerumen. Thus it behooves us in every case of wax in the ears to search diligently for the cause, and especially to examine the condition of the middle-ear and naso-pharynx. Yet in my own experience most cases are without any discoverable cause.

Methods of removing wax need little description. In the great majority of cases the syringe and warm water properly used are amply sufficient. When there is desquamative inflammation of the canal the syringe often fails, and I find most satisfaction in the use of Buck's curettes, delicate forceps, and occasionally a small hook; but instruments are seldom needed, and should be used only by one accustomed to aural practice. One case was reported where syringing was found insufficient; a large mass in the left ear whose central portion wax, was but whose chief bulk was made up of dried skin, the result of a desquamative inflammation, had to be gradually and laboriously picked out with curette and forceps, softening it a little with a solution of bicarbonate of soda. When the wax has been removed, we often find the canal slightly inflamed, with a tendency to desquamation. In such cases a little yellow oxide of mercury ointment (gr. i to vaseline oz. i) is an old-established and valuable remedy. When there is much scaliness and itching, oil of Cade (oz. i. to vaseline or olive oil oz. vi.), may be used with advantage.

*Diffuse inflammation of the Auditory canal,* varies widely in its symptoms and its causation. Leaving out of view those cases which occur as complications of middle ear disease, we find irritation from picking at the ear with hair pins, ear spoons, etc., among the most frequent causes. The inflammation may be gouty; it is often eczematous; it is rarely diphheritic.

Roosa states that the symptoms in the

*Read before Louisville Medico-Chir. Soc., 1893.

order of their occurrence are: itching, pain, and a sense of fullness and heat. To these I would add in many cases pain in the movements of the lower jaw. Objectively we find deafness, redness, swelling, and later often suppuration. The most variable of all symptoms is pain. Its degree depends chiefly on whether the inflammation is in the cartilaginous portion of the canal only, or involves the bony also. In the latter case it takes the character of a periostitis and is often most intense. Indeed, even the agony of acute suppuration of the middle ear is not greater in severity, and is more easily controlled than that of severe inflammation in deeper parts of the auditory canal. The most intense cases of this character which I have seen, have been in ladies whose general health was debilitated. Next to pain the deafness and itching give most annoyance. The former depends on the obstruction and varies with the degree of swelling; the latter (itching) is usually the first symptom, and the rough means used to relieve it by the patient often greatly intensifies the inflammation. Occasionally there is a mastoid periostitis complicating disease of the canal. It is manifested by the usual symptoms, but need not give the same anxiety as when it attends disease of the middle ear, as the inflammation is almost always confined to the periosteum.

In the treatment of this disease we, of course, look first for any constitutional cause such as gout, syphilis, etc. As regards local treatment: There are two points as to which experience seems to differ greatly. They are the use of poultices and the value of early incisions. It is contended by many eminent aurists that continued poulticing gives rise to granulation tissue, and does more harm than good. Thus Roosa says,—"A poultice should never be applied to or on the ear for more than a few hours. They are almost as dangerous a remedy in aural as in ophthalmic practice, etc." I have not found this the case, except when used after an incision or the opening spontaneously of an abscess. For the relief of pain and to subdue swelling, there is in my experience no substitute for the poultice, but when there is free discharge it should be discontinued. Next in value to poulticing is hot water allowed to run into the ear from a fountain syringe. The piston syringe should not be used; its force is painful. It is often well to use the poultice and hot water alternately. A salve of cocaine, menthol and carbolic acid I have found of some service in allaying the pain and itching. Of course when there is free discharge the first indication is thorough removal of this. In such cases application of nitrate of silver gives the best result.

As regards incisions into the swollen tissue: I have found them useless except to evacuate pus. The circular shape of the auditory canal holds the cut surfaces constantly in contact and prevents the relief that might elsewhere be obtained from the lessened tension. When the incision is to be made, a few drops of a four per cent. solution of cocaine should be injected hypodermatically—the syringe being used through a good sized speculum. A curved bistoury is the best instrument for the purpose, carried in over the point of greatest tension and cutting outward. With the use of cocaine this little operation is almost painless; without it, intensely painful.

In obstinate cases a blister on the mastoid is sometimes useful. Leeches, invaluable as they are in acute suppuration of the middle ear, have but little control over inflammation in the auditory canal.

I desire to report one case recently met with in practice, in connection with the paper. The patient was a gentleman about fifty years of age, who this summer had an attack of erysipelas affecting the auditory canal of the left ear. I did not see him in that disease, but did see him about four weeks after his recovery. I found the canal inflamed and swollen, and there was a slight discharge. I tried first, nitrate of silver and later all the well-known routine remedies. Although there was swelling, I did not believe there was any pus to be evacuated. I applied a blister behind the ear, as this sometimes produces a favorable result. Also used Fowler's solution internally, without effect. Finally I made an incision into the auditory canal, and without my advice the patient used hot applications for a while afterward. The result of hot applications following incision, was growth of granulation tissue in the canal. The patient left the city shortly after this and I have not seen him since. I report the case simply to show the obstinacy of some of these affections of the auditory canal; they are not dangerous yet, as this case shows, they are sometimes exceedingly tedious.

## CHRONIC RETRO-BULBAR NEURITIS.

W. CHEATHAM, M. D., A. B., Louisville, Ky.

[CONDENSED.]

The true pathology of this affection was not well understood until the first demonstration in an autopsy by Samelsohn, in 1882.

Leber, Michel and others had referred to it before, but had never demonstrated the fact by autopsy. It has been demonstrated "that the marginal fibers of the disc ends in its immediate vicinity, and, in general, the central fibers go to the periphery of the retina, while the peripheral fibers of the disc supply the central part of the retina; the papillo-macular fibers entering the eye as a wedge-shaped cluster on the temporal side of the disc occupying nearly its inner and lower quadrant."

As the title of the paper implies it is only the fibers of the optic nerve in front of the chiasm that are involved generally.

*Causes:* The principal cause is alcohol or tobacco, alone or combined; some authors say it is tobacco alone, the alcohol acting only as a depressant. Of 138 cases, 64 were from alcohol, 23 from tobacco, 45 from tobacco and alcohol combined, diabetes 3, lead 1, and sulphuret of carbon 2; other causes as cold, and especially cold blasts on the face, chloral, stramonium and syphilis are given by Swanzy.

*Symptoms:* The failure of vision is so slow usually that the patient does not discover it until it is well advanced. Only this week, a man came in with tobacco-alcohol amblyopia, whose vision was but half of perfect. The patient complains of seeing as if he were looking through smoke or a veil. The vision of the two eyes is usually about the same, which is a point in differentiating it from disease of central origin. In the beginning there is no trouble with the field of vision; later on though, there will be discovered a central negative scotoma for colors, especially green and red. This scotoma is usually oval in shape with the long axis horizontal.

The retina involved being that portion extending from the temporal edge of the disc to the outer edge of the macula. Later on the perception of white will diminish in this area, and if the disease progresses may be entirely lost. Vision is often reduced to almost nothing in this affection, but total blindness is exceedingly rare.

It is not the periodical drunkard who is liable to suffer from this trouble, but the sipper, or steady drinker, or more often the fellow who never gets drunk. The disease is more common in the male than the female, in the old than the young, for reasons easily understood. Some author has stated that it does not occur in persons under twenty years of age, yet I have a patient now only sixteen years old; cause, the abuse of tobacco and beer.

A peculiarity of the disease is that a person may be nearly blind from tobacco-alcohol amblyopia, who under treatment may recover vision, then return to his old habits, and exceed even the abuse formerly practiced, and yet have no relapse.

The ophthalmoscopic symptoms, especially in the early stage of this disease are usually negative; the optic disc may be a little hyperæmic, or present what I used to call a brick dust color and granular appearance; later on the temporal half of the disc becomes quite pale. A point in differential diagnosis I have seen made somewhere, just where I cannot now recall, is that by the inhalation of a little amyl nitrite, vision is much improved for a while. I tried this last week on a gentleman about sixty years of age, whose vision was only $\frac{1}{4}$ of perfect, the result of alcohol and tobacco abuse, especially the latter. I told him to look at the test card, and passed under his nose a glass stopper with a drop or so of the amyl nitrite on it, and he immediately exclaimed with much joy that he could see as well as ever. He demonstrated the fact by reading $\frac{1}{1}\frac{1}{1}$ or more than required in a test for perfect vision. How long this lasted I do not know as I have not seen him since. Strychnia hypodermatically in a large dose may have the same effect.

The pathological changes, as given by Samelsohn and others, in the optic nerve consists in an interstitial neuritis at its axis, commencing outside of the chiasm, preferably this portion of the nerve, and

leading to proliferative of connective tissue, and to secondary atrophy of a certain bundle of nerve fibers; the changes are analogous to those which take place in the liver and brain as the result of chronic alcoholism.

*Treatment*: The first indication is, of course, to correct the cause; promises to do so are easily gotten and as easily broken. A majority of the cases, if not too far progressed, will recover with no other treatment than the correction of the cause. Again others will need the leech, turkish bath, and strychnia; the latter preferably hypodermatically. I usually order strychnia nitrate gr. iv; aqua, ounce one—each drop contains gr. $\frac{1}{120}$ of the strychnia. I commence at gtts. ii, and increase one drop per day until the physiological effect is reached, which may be anywhere from gtts. xv to gtts. xl. Pot. Iod. is indicated also, or I often give zinc phosphide and strychnia, in pill,

## CASE OF PARALDEHYDE HABIT.

T. H. STUCKY, M. D., Louisville, Ky.

I would like to report a case of paraldehyde habit. The latter part of April I was called to see a young woman twenty-one years of age, who had previously been addicted to the use of morphine. She had been in Illinois attending the Keely Institute and had been relieved partially. I found her very restless and nervous, and prescribed valerian and assafœtida, but she was unable to take it. I then ordered three ounces of elix. paraldehyde, (Flexner), saw her the next day, when she seemed much better, and told her if she had any further trouble to let me know. I heard nothing more in regard to the case until, I think, the latter part of September, when her husband came to me and asked if his wife could not stop taking that stuff; that she had had the prescription doubled in May and filled ten times—which was sixty ounces; in June had it filled sixteen times—which was ninety-six ounces; in July filled twenty times—making one hundred and twenty ounces; in August filled twenty-three times—one hundred and thirty-eight ounces; September filled thirty times—one hundred and eighty ounces.

I went to see the patient and she stated that she drank the medicine from the bottle whenever she began to feel a little faint or nervous. I was surprised to learn that it still produced sleep and gave her decided benefit apparently, but the most interesting feature was, that I could not see it affected the heart to any marked degree. It produced absolutely no alarming symptoms, and her appearance was similar to what we see in a person addicted to strong drink—she resembled an individual who had been on a protracted spree. The paraldehyde was withdrawn the first of October entirely. She was placed in bed and watched carefully by a competent nurse, and I gave her valerian and strychnine. She seems to suffer just as one who is recovering from delirium tremens.

This patient consumed an average of six ounces of paraldehyde a day, or one hundred and eighty ounces during the month. I have never seen report of a case of this character and it struck me as being very unusual.

---

One of ex-Senator Evarts's Stories.—To Mr. W. M. Evarts belongs the anecdote of the bereaved widow whose husband had such a large circle of friends that the company which she received on the evening of his interment crowded her drawing-room almost to suffocation. A lady friend of the widow edged her way up to her, and, pointing to something very bright and shining visible above the heads of the assembly in a remote corner of the apartment, whispered in her ear, "Say, is that a new eight-day clock? What d'ye gin for sich?" "It's not a clock," sobbed the disconsolate widow: "It's the dear departed. We sot him on end to make room for more company." The supposed eight-day clock was indeed the "casket," richly ornamented with silver nails, bosses, and handles, to which the dear departed had been consigned.—G. A. Sala, in *London Telegraph*.

## RETENTION OF URINE WITH HÆMATURIA.

OSCAR LEEDOM, M.D., Plymouth Meeting, Pa.

J. D. A large, powerfully built man, about fifty years of age, was taken sick with retention of urine on the 18th day of November, 1892. He had been husking corn and was on the damp ground from early in the morning until late in the evening. During the four succeeding days he managed with great difficulty, to pass a little urine, but continued at his work until the 22d, when the retention was complete, and he sent for me.

I found the patient in great distress, unable to pass a drop of urine, and the bladder tremendously distended. Upon introducing the catheter I drew off a great quantity of urine. From this time on, he had no control of the bladder whatever, the catheter having to be used twice daily. There was no pain except when the bladder became distended with urine; no tenderness upon pressure, nor any burning along the urethra.

He continued in this condition about two weeks, when, suddenly, his urine became bloody and he began passing great quantities of jelly-like mucous. This was accompanied with intense burning and distress. The pain grew severer as the bladder became empty every time the catheter was used. The urine was reddish-yellow or bright-red, at times followed by the discharge of nearly pure blood with the last few drops of urine. This continued about five days, when the urine began to clear up, the mucous disappeared and the urine returned to its natural color. The pain and burning ceased and he seemed in a fair way to recover.

A day or two after, however, the same symptoms returned in all their former intensity. The urine became bloody, filled with mucous, and loaded with shreds which looked like exfoliations from the mucous membrane of the bladder. The burning and distress returned. In a few days the urine again cleared up, to be followed by a similar recurrence after an interval of a few days. So long as the urine remained clear the patient was quite comfortable, slept well, and was comparatively free from pain. The retention still continued, necessitating the use of the catheter twice a day.

He continued in this condition until the 20th of December, when he began passing urine in the natural way. Dec. 24th. "Passes urine without much difficulty. Urine slightly cloudy from presence of small quantity of mucous. No albumin; clears up upon boiling." (The urine was not examined at any time with the microscope.)

This case was of considerable interest to me, and presents some remarkable features. The diagnosis was not clear. I feel positive that the hemorrhage was vesical, but the origin of it was not at all clear. Coming on as it did so suddenly, stopping and then recurring, to eventually cease with the return of health. The presence of a tumor, either villous vor malignant, seems out of the question. There was no history of malaria, and the absence of pain or tenderness upon pressure over the region of the bladder, seemed to exclude any serious inflammation of the mucous membrane with ulceration or necrosis. The prostate was not enlarged to any extent.

The treatment consisted in washing out the bladder twice daily, with warm solution of boracic acid and injecting a solution of glycerole-pepsin, the object being to dissolve the jelly-like mucous which came away in great quantities. Internally ergot and ex. uva-ursi were given, with morphia to relieve pain. The patient recovered entirely and has never suffered any bad effects from his illness.

---

The nationality of Pasteur's patients is an interesting item. France and Algeria sent him 1,584 in 1892, and Algeria is notorious as a source of supply of bitten persons. Portual sent 96, England 26, Belgium 11, Egypt 12, Spain 14, Greece 19, Russia and the United States 1 each, Holland 14, Switzerland 3 and India 9. In Russia and elsewhere, I fancy, they have institutes of their own for the practice of Pasteur's treatment. From Madeira one patient came, his injury arising from a rabid dog which had been bitten by a Portuguese dog. Till then rabies was unknown in Madeira.—*Illustrated London News.*

## THREE CASES IN SURGERY.

C. S. COPE, M. D. Ionia, Mich.

Case I.—I was called March 31, 1890, to treat a fracture of the elbow, and found a patient with the following remarkable history: In 1820, while he was a young man of 21 years of age, he was engaged in chopping in the woods of the Empire State. Unfortunately an ax slipped from the hands of a fellow-woodsman, and inflicted a severe wound on the dorsal aspect of the left arm, nearly severing it at the elbow.

After suffering much at the hands of many doctors, he finally recovered, but with a stiff arm, obtusely flexed at the elbow. By use of shoulder and wrist, he was again able to handle his ax. But for seventy years he went through life thus mained.

At the time I was called, he had met with an accident. By slipping on the floor in a store, whither he had gone to make some purchases, he had fallen heavily, his weight coming on the crippled elbow, producing a complete fracture through the joint. Careful attention was given, but the bones did not unite. He made much complaint of the doctors of the present time, and lauded to the skies the good old doctors of the past.

But, lo! a change came over the spirit of his dream, when, after the pain and soreness were gone, he found that he could bend and extend his arm. It was with difficulty we convinced him of the fact that, instead of a return to natural conditions, we had simply a false joint, made so by the non-union of fractured bones. It was amusing to see him raise the left hand tc his head and stroke his face, a privilege he had been debarred from for so long. He lived two years after that in the enjoyment of his new elbow and passed away last winter at the advanced age of 93 years

Case II.—On the 13th of September, 1891, I was called to see Rachel P., an old lady of 89 years, who had fallen from a porch, and sustained a transverse fracture of both bones of the right forearm, two and a half inches above the wrist. Being thin in flesh, the fragments of fractured ends easily movable and the crepitus and deformity very distinct, the diagnosis was made at a glance.

The fracture was reduced at once, roller bandage applied, and with other indicated treatment she was quite comfortable.

The patient was demented and had been so for many years. This made it difficult to keep the limb in proper position, for she would at times loosen and remove the bandages. Finally we were obliged to muffle the well hand, to prevent further trouble. We gave it as our opinion that the bones would not unite, owing to her extreme age. But to our surprise, provisional callus was thrown out, and the bones made a complete union.

There was no doubt of this, for after six weeks she would, unaided, rise from her chair by placing the right hand on a table and bearing heavily, assume the erect posture.

But on December 13th, just three months from the date of the injury cited, the fracture was put to a crucial test. Wandering aimlessly about the house she came to the cellar door. This she pushed open with all her force. It opened inward, and giving way from her pressure, she was precipitated headlong down thirteen or fourteen steps to the depths below. Her groans brought speedy help, and the doctor was called in haste.

We found the right shoulder dislocated, while scalp and skin wounds and bruises were numerous. In fact, it seemed as though scarcely a part of the surface escaped contusion, but strange to relate, the fractured arm came out all right, although it was evident that this was the one advanced to save her as she fell.

The dislocation was reduced and the wounds attended to. She made a good recovery from the shock, and did nicely for two weeks, when she was seized with the grippe, to which she speedily succumbed.

Case III.—On the 19th of January, 1892, Mrs.—, was walking briskly over a broad stone sidewalk which was encrusted with ice. Her feet slipped, flew skyward and she struck heavily on her right hip. The fall was a bad one, and she was severely injured. Woman like she scrambled up, and looking to see if any one had observed her mishap, went on to her destination, and returned to her father's office

in the next block, to reach which she had to ascend a long flight of stairs. She was very pale and suffered great pain whenever she attempted to walk.—We must go back a little and state that just before leaving the office, her husband had made her a present of a new lead-pencil, which he had nicely sharpened. This pencil was carried in the pocket of the short coat she wore at the time of the accident.—When she reached home that evening she found blood on her underclothing. There was a circular wound in the skin about the centre of the buttock on the right side. The clothing was also fonnd to be perforated in places. A hole was also found in the pocket of the coat. One half of the lead-pencil was found in the coat pocket. This piece of the pencil looked as if it had been forcibly broken in two, as the end was splintered and irregular.

Search was made for the missing piece, but it could not be found. Supposing that it was in the wound, a physician was called, but could afford no relief, as the patient was nervous and apprehensive, and would not allow a thorough examination to be made.

The following evening I was called to take charge of the case. The patient had been walking around aided by crutches, and had thus caused considerable pain and distress.

By use of cocaine the wound was made painless, and a probe was passed to the depth of five inches. The wound was to the inner side of the trochanter major, nearly over the hip joint. The probe entered this and passed inward and upward toward the dorsum of the ilium.

The patient would not consent to chloroform, and was too nervous to undertake an operation without, so proceedings were stayed. We could only bide our time, and, departing, left word to recall us when she was ready to have it removed.

After much suffering, and when the wound began to discharge and smell bad, we were again summoned, and on the 11th of February relieved her of a piece of large-sized lead-pencil, three and three-fourths inches long. We had to carry the knife two inches deep to reach it, and make the wound sufficiently large to explore it with the finger, when the pencil was at once located and easily withdrawn.

Its sojourn of twenty days had sufficed to remove nearly all the paint from the pencil. There was considerable discharge of ill-looking, offensive pus.

The wound was injected daily with Marchand's peroxide of hydrogen, and the patient made a rapid recovery.

---

**Preservation of Leeches.**

A subscriber writes that he received some leeches on one of the coldest days of the present winter; when he opened the container, he found them frozen stiff. He then put them into cold water, which apparently brought them to, as at the date of writing they were "lively." He now wants to know whether they will bite and draw when used. It is said that extremely cold weather sickens the leech and makes it inactive. The most satisfactory way for you to decide the question perhaps would be to make a trial with one or more of them. The following directions for the preservation of leeches may give you some information on the subject: As soon as the leeches arrive from the dealer, they should at once be removed from the box, and washed thoroughly in soft water, which should be at 60° F. The first washing rejected, they should then be placed in a jar half filled with water about the same temperature, with a piece of clean muslin placed over the mouth of the jar and covered with a perforated lid. Care must be taken that the water replaced be no colder than the water rejected or thrown away. The jar should be well cleansed inside every day or two in winter, and every day in warm weather, thus preventing the accumulation of any foreign matter along the sides of the jar, and the leeches taken out and gently rubbed between the fingers, or between the folds of a soft cloth to free their bodies of the mucous or slimy substance which envelopes them. You should guard also against the access of acrid vapors which may come in contact with the jar, such as ammonia, gas, and the vapor of mineral acids, which by their density finds a ready means of access through the porous lid to become absorbed by the water in the jar, which, after a short time would result fatally. If these precautions are carefully taken the leeches may be kept in a fine state of health, and there would be no likelihood of trouble in getting them to bite readily when applied to any part of the body.—*Pharm. Era.*

# TRANSLATIONS.*

## ACUTE RETROGRESSIVE MUSCULAR ATROPHY.

Dr. Adam Kilwicz (*Prag. Med. Wochen.* 1893) says: "All forms of muscular atrophy, either of myopathic or nervous origin, finally tend toward one end—death after a longer or shorter period." The author reports one case in which he shows that the myopathic form is occasionally able to take up a retrograde metamorphosis and end in a cure.

The patient, æt 28, having passed a healthy childhood, was never neuropathic; suffered during her third pregnancy with a grave attack of hyperemesis, making it necessary to feed her per rectum, since her stomach refused to retain anything. One day she had the misfortune to fall from a chair upon which she was sitting; she was unable thereafter to make the slightest movement.

A careful record shows that she was attacked by acute muscular atrophy of the myopathic form, having the peculiarity that the atrophy did not confine itself to the upper (*typus facio-scapulo-humeralis*) or to the lower (*typus-femero-tybalis*) extremities alone, but attacked upper and lower at the same time. The muscles of the balls, and all extensors, and, above all the min. peronæi were included.

It was quite interesting to note that as soon as the comparatively easy labor had been completed, a decided improvement took place; the contractions of the antagonized muscles became daily less, and slight movements of the affected muscles became possible. On the fifth day after parturition the patient was able to sit up; on the eighth day she could support her weight standing, and after the second week was able to walk with some assistance.

After the lapse of a few months the only traces of her illness left were the condition of the balls of the thumbs and the atrophy of the interossei muscles of the hand.

The author believes that the changes necessarily following in a pregnant uterus, proved the main factors, together with the lack of assimilation of nutritive principles, in producing the attack of muscular atrophy. This can, however, be explained only under the head of reflex actions.—*Centralb. f. d. Med. Wissen.*, 93.

—W.

## THE TREATMENT OF PRURIGO BY MEANS OF MASSAGE.

Dr. R. Hatschek, Vienna, (*Arch. f. Dermat. u. Syph.* 1893, xxv., p. 931), reports the result of eleven cases treated after the method described by Murray. Seven of these belonged tor purigo agria, and four to prurigo mitis.

The proceeding consists of simply rubbing the affected area, beginning at the peripheral end of extremities and rubbing toward the centre. The time required for one treatment, during the first few days is from ten to fifteen minutes. As improvement takes place this may be reduced to from five to three minutes. In all cases this treatment was followed by prompt relief of the troublesome itching, and a visible improvement in the infiltration of the skin.

In some cases there was a return of the small nodes, which, however, disappeared promptly after the vigorous use of massage. Two to three weeks seemed to be sufficient to produce a complete disappearance of the disease; while an occasional use of massage seemed sufficient to prevent a return.

The cases in which eczema formed a complication, massage appeared to act as an aid in its cure.—*Central f. d. Med. Wisen.* Nov., 1893. —W.

The autopsy in the case of Prince Alexander of Battenberg showed that the original cause of his illness was the lodging of a cherry stone in the vermiform appendix.—*Pub. Opinion.*

## EDITORIAL.

### TUBERCULOSIS IN ITS RELATIONS TO THE PUBLIC.

During the meeting of the Pan-American Medical Congress last September, the Section of Hygiene and Climatology unanimously adopted resolutions urging upon the governments of the nations represented, the necessity of enforcement by public authorities of measures directed to the limitation and prevention of tuberculosis. As might be expected, in view of the active public consideration of preventive and sanitary questions excited by the imminence of a cholera epidemic, these resolutions widely attracted attention among health authorities. Recently the State Board of Health of Michigan has announced that it will enforce throughout the whole state, the registration of tubercular cases and the disinfection of the dwellings and surroundings of sufferers from this disease. The Board of Health of the City of New York had already adopted the same precautions. Immediately after the adjournment of the Pan-American Medical Congress, the Philadelphia County Medical Society, with due deliberation and after a full discussion, formerly endorsed the judgment of the Section of Hygiene and Climatology, and appointed a committee to urge upon the Board of Health of Philadelphia, the requirement of registration of tuberculous patients and the disinfection of apartments occupied by such cases, after the removal of the occupant The matter attracted considerable public notice and afforded the daily papers an opportunity for the display of their scientific acquirements. It likewise afforded a few individual members of the city profession a chance to expose the incapability of the congregations of alleged experts, known as this or that section or society, while posing themselves before an admiring audience. The resolutions of the County Medical Society have gone into retirement, nor has any action been taken by the Board of Health. The presumption is the officials are studying up the matter with the aid of the lexicon and the quiz-compend.

The recommendation of public measures for the limitation of tuberculosis is receiving the careful consideration of health authorities of all parts of the United States, and there is good reason to hope that some public precautions will be enforced in every

state in the Union, perhaps, at no distant day.

It cannot be entertained for a moment, that the action of the section of the Pan-American Medical Congress, the Philadelphia County Medical Society and kindred associations of medical men of the highest intelligence and scientific knowledge, was taken with any undue haste or without thoughtful consideration of the difficulties and inconveniencies involved, without a full knowledge of the necessity of some practical precaution, or without deliberate determination to succeed eventually. The movement for the public limitation of tuberculosis is neither a sensation nor a fad. It is the inevitable outcome of the indefatigable spirit of research carried on with experiment and observation, by trained minds with all the modern appliances of precision at their disposal. It is not the dictum of any one observer supporting a theory, or of any small number of observers engaged in upsetting theories, but it is the consensus of opinion of medical scientists slowly crystalizing from the experiences and observations of all science.

It is not claimed that our knowledge of tuberculosis is complete—far from it; but the last dozen years have shown a marvelous amount of exact knowledge acquired by scientific experimentation and most minute observation, with the resultant accuracy of conclusions. In the realm of medical science, perhaps no demonstrations have been more conclusive than that tuberculosis is an infectious disease, whether it occurs in man or other animal, and that tuberculosis is practically never directly transmitted through heredity.

It now seems ascertained that heredity plays no part in the development of human tuberculosis, save the possible transmission of an increased susceptibility to the disease, which must, however, arise from specific infection after birth. Furthermore, it is not possible for tuberculosis to develope in the human system, no matter what the degree of susceptibility may be, without the introduction of the specific infection. There is no doubt that, as a general rule, repeated exposures to infection and a degenerate condition of the tissues invaded by the infectious material are required for the development of the disease. Almost any tissue in the human body is liable to invasion by tuberculosis in one form or another.

The lesions of tuberculosis are invariably associated with and probably caused by the local irritant action of a specific bacillus. This, the tubercle bacillus, is endowed with high vitality and great irritant qualities, though even under favorable conditions they multiply relatively slowly. While they have been cultivated artificially outside of the body, it is very sure that natural external conditions favorable for their reproduction are rarely or never present, but there is abundant proof that their virulence and power of propagation can remain latent for an indefinite time under these same external conditions. The discharges or secretions of tuberculous patients contain these bacilli in enormous numbers and constitute the media of infection. The bacilli do not occur either in the expired breath of a tuberculous person or in the exhalations of the body. So long as the secretions and expectoration of tuberculous persons retain moisture sufficient for cohesion there is no danger of infection. The bacilli cannot separate themselves from the medium containing them. But let these secretions become dried and pulverized and mingle with the dust of the atmosphere, and the tubercle bacillus has opened up to it an infinite field for operation.

This is the matter in a nut shell. Everything that comes in contact with a careless or ignorant tuberculous patient may become thoroughly infected and, in more or less degree, a constant

source of danger to those who associate with him. And when for any cause the dwelling of a tubercular case is vacated the source of infection remains in the dwelling to menace the life of future inmates unless the destruction of infectious material is accomplished by thorough disinfection. Recent researches by Dr. Flick of Philadelphia, made, in a most thorough and scientific manner, prove beyond peradventure that in dwellings known to be infected, family after family occupying them in turn, have suffered unusually from tuberculosis.

Concerning the proposed measures for limiting and preventing the spread of tuberculosis, *The Dietetic and Hygienic Gazette* for the current month says editorially:

"In so far as the propagation of the disease from man to man is concerned, the means of safety are simple, reliable and practical; but they involve the necessity for the honest and willing co-operation of the sufferer, his attendants, his physician, and the local board of health. The watch-words of safety are *registration, disinfection!* Destroy the infectious discharges at the earliest possible moment; never allow them to become dry.

Thoroughly and periodically disinfect and cleanse the apartments occupied by the sick—disinfect, before washing, his bedding and clothing, especially the handkerchiefs. After the apartments or dwelling occupied by a consumptive are vacated, either by death or removal, thoroughly disinfect and cleanse them before they are occupied by others. It is not our function to elaborate this fundamental principle of disinfection, nor have we space here to discuss its details. These, as well as other precautions, should be left to the intelligent family physician and the board of health. Anything like quarantine or restrictions of liberty of movement of consumptives, is entirely out of the question, and would, moreover, be quite impossible. On the other hand, to instruct the attendants as well as the patient in the importance and the mode of disinfection of the infectious discharges necessitates no hardships and need add nothing to the discomfort or mental anxiety of the unfortunate victim. Indeed, so soon as the consumptive becomes convinced of the absolute necessity to promptly destroy the expectoration, the chance of the individual's recovery is that moment materially brightened, for then the constant danger of repeated auto-infection is gone. What well-informed physician does not know that the disease, already at work in the lungs of his charge, is liable to spread by further infection through constant inhalation of dust carrying tubercule bacilli already thrown off from the very same lung? What experienced physician or pathologist does not know that to cough up sputum from a tuberculous lung and to swallow it instead of expectorating is to enhance the danger of engraftment of an abdominal tuberculosis upon that which already exists in the lungs, and make both more certainly fatal? Down, we say, with the puerile and senile cant we sometimes hear in opposition to registration and disinfection for the limitation of human tuberculosis! It is injurious alike to the suffering patient and to the general public.

A practical, judicious application of modern knowledge concerning the nature, mode of dissemination, prevention and management of tuberculosis would minimize the terrors and dangers created by it. This mortal enemy of man, although he has decimated our race for ages, is not a herditary conquerer. We have at last learned his tactics and stratagems, and have discovered the armor which renders his shafts harmless and the arms by which he can be routed. We can also cover those already wounded with an ægis of protection which will save many even of them from death. Should we longer hesitate to put on this armor and take up these arms in defense of mankind?"

# ABSTRACTS.

## THE ERECTILE TISSUES—THEIR PHYSIOLOGY, PATHOLOGY, AND TREATMENT.

Dr. J. J. Caldwell (*Charlotte Med. Jour.*) says: There are certain parts of the body, male and female, which, when excited, become swollen and turgid with blood and firm to the touch. The sensibilities, and indeed all of the actions of such parts appear exalted when in a state of erection. The most peculiar phenomenon in this state is the sudden and remarkable accumulation of blood in the erectile tissure at the time and as the immediate cause of the erection.

This action was formerly explained by the existence of a certain force peculiar to erectile tissue called "nervi-erigentes;" but the researches of later physiologists have discovered a peculiar mechanism in the tissue itself, by means of which the elongation is produced, viz: it depends upon pressure exercised on the veins or sinuses of the tissue by certain bands of muscular fibres; and hence the accumulation of blood as the arteries convey it freely and rapidly to the tissues. These muscular bands are supplied by nerves in much the same way as the vessels from centres located in the spinal cord, and are often called the "nerve-erigentes." But no matter whether the congestion is produced by the action of the vaso-dilator or the vaso-motor apparatus, or by direct or indirect action on the muscular appartus of the erectile tissue, we must in any case refer any influence transmitted to the parts in question to the spinal cord. This leads us back to a genito-spinal centre in the cord, vaso-motor, but as we have seen before, no nervous centre can act of its own motion, or originate action *de novo*, they must be excited to action. This being so we must look about for a suitable excitant influence to act upon the vessels so as to cause, in one way or the other, congestion. For a long time it has been regarded as probable that the spinal cord has a direct influence on the organs of generation; but it was Budge who made the definite experimental observation in regard to the influence of the lower part of the spinal cord on the motions of the generative organs. He laid bare the spinal cord in a male rabbit and at the same time exposed the testicle, the *vas deferens* and seminal vessel of one side. By irritating the exposed lumbar portions of the cord he found in numerous experiments that irritation of that part which corresponds to the fourth lumbar nerve produced active motions in the *vas deferens* and seminal vessels, the motion beginning at the testicle and being propagated toward the corresponding seminal vessels. The irritation on no other part of the cord produced such effects. These observations on the male, which have been often repeated with the same results, have also been made on the female; and movements of the uterus have been excited from corresponding points of the cord, therefore, the development and escape of the seminal fluid and graafian vesicle are attended with no small degree of nervous excitement. Actuated from the same spinal centre, both male and female, organs of generation becomes more and more congested and irritable as these phenomena increase, so that every impression, even every influence affecting these parts must be reflected to and from the spinal cord, from these to the brain and to the external genitals; hence we may readily perceive the relations existing between potency and the vaso-mator tonus of the genito-spinal centres, or impotency and the plexuses of these centres. In the latter case there could be no erection or there would be a great loss of the fluctuating powers of the genital organs, i. e., enfeeblement of secretions, erections and ejaculations of the male and a want of activity and ovulation and menstruation on the part of the female. Hence, all of the procreative powers are more or less dependent upon the aforesaid vaso-motors. The inhibitory action exerted by these sensory centres thoroughout the cord play a vitally important influence over the circulation, viz: periodical and rhythmical action of the heart and respiration, blushing, rage, pallor, and suffusion. Says John Hunter: "There is not a natural action of the body, whether voluntary

or involuntary that may not be influenced by the peculiar state of mind at the time."

Impotency in man may be caused by absence, want of development, malformation, or mutilation of the penis; by mental influence, any violent emotion operating protractedly or during coition, as want of confidence, fear of consequences, anxiety, grief, disgust, over excited desire.

By fevers and other severe diseases, the sexual organs remaining feeble after general health is restored. By injuries to the back part of the head from falls, blows, concussion, etc.; these being generally incurable, loss of power and wasting of testes and penis follow. By injuries and diseases of the spinal cord, which remove the power to copulate though desire remains and semen may be secreted. By excessive use of tobacco, which impairs digestion, and weakens nervous and muscular systems. Opium eating is injurious in like manner and from the same cause. By abuse of the sexual functions, removing the power of erection. Onanism or excessive sequal intercourse. Spermatorrhœa. Impediments to escape of semen, such as stricture of urethra in which the ejaculated fluid regurgitates into the bladder. Abnormal openings in the urethra (hypospadias and epispadias) so that the semen is not ejaculated into the vagina. By excessive obesity and large scrotal hernia.

Impotence in women may be due to firm adhesions of the *labia pudendi;* excessively developed and persistent hymen; absence, malformation, or an impervious condition of the vagina; obliteration of this canal through inflammation. A double vagina impedes but does not prevent copulation. Super-sensitiveness with spasmodic closure of the vagina (vaginismus). Tumor of the vaginia, or uterine tumors which have passed into the vaginal canal. Elongation of the cervix uteri; engorgement or induration of *labii uteri;* obliteration, obstruction, or great narrowing of os uteri or cervical canal. Closure of uterine cavity by tumors, cancers, etc. Malposition of the uterus. Acute retroflexion and ante-flexion. Inflammation affecting the uterus. Occlusion of the fallopian tubes, disease of fimbriated extremities. Irremediable procedentia of the uterus. Large recto-vaginal or vesico-vaginal fistula, or complete rupture of perineum allowing improper escape of seminal fluid. Uterine cancer, even when the vagina is involved, impedes but does prevent intercourse and fecundation.

Sterility in man arises from certain diseases, such as tubercolosis, diabetes, albuminuria, some forms of obstinate dyspepsia; in advanced stages the secretion of seminal fluid is usually stopped. Some cerebral defect, owing to which the functions of the testicles have never been called into play. Disease of testicles, tumors, cancers, repeated attacks of varicocele, though as only one gland is usually affected, these conditions scarcely produce sterility. Malposition of testes, these organs being retained in the abdominal cavity copulation being feasible with the crypsorchis, but the semen ejaculated being destitute of spermatozoa. Obstructions in the excretory ducts of the testicles; such as temporary or permanent obstructions after epididymitis, with power of copulating, but ejaculated fluid being destitude of spermatozoa. Obliteration of ejaculatory canals from abscesses near prostate leading to atrophy of the testes. Abuse of tobacco, opium, and alcoholic drinks, and syphilitic taint as well, may destroy vitality of spermatozoa.

Sterility in women arises from amennorrhœa; from exhaustion or excessive general weakness; too frequent or imperfect sexual excitement, and those versions, displacements, congestions, hysterias, paralyses, tumors, which are the prolific results of masturbation. Absence, arrest of development, or disease of ovaries, only occasional, not absolute cause, as both glands are seldom diseased at the same time. Leucorrhœa, especially when the discharge is abundant and acrid, by causing destruction of the spermatozoa before they reach the ovule. Syphilitic taint occasionally destroys vitality of ovule. In the absence of all obstructions or indications of disease, with apparent perfect moral and and physical adaptability, there are cases of sterility still existent, regretable and baffling, which if not irremedible, their hope and succor rests solely in the studious skill of the neurologist. How momentous a medico-legal precaution may be the services of such an expert in family imbroglios, dubious and unjust dismemberments of estates, prevented litigations depending upon the want of that 'glory'—an heir—is attested frequently by memorable and gratifying solutions.

TREATMENT.

While these tissues in their pathologic state may demand sanatory means and applications as comprehensive as sexual neurasthenia, with its mental hygiene electro-theraputy, baths, massage, counter-irritants, and the like, along with the well-known older remedies, I include as valuable and reliable, for the actions they are sought to produce, the following remedies: Damiana, yerba santa, saw palmetto, liquor sedans, vanilla, black haw, pichi, stylosanthus elatior.

A few cases may illustrate and break the monotony of more general assertion.

*Persistent Spermatorrhœa.*—Mr. H., of North Carolina, aged thirty, married several years without issue, owing to his persitent spermatorrhœa, which incapacitated the full act of copulation and deteriorated the vitality of the seamen. Upon presentation I found that his urethra along the whole canal was very irritable, particularly so along the prostatic portion; that the organ was continually weeping spermâtic and prostatic fluid, and that he suffered ejection during the slightest irritation, mentally and physically, and that he was melancholly and foreboding, and that his skin was cold, clammy and sallow. His general health was very much broken. He had married with the hope of benefitting these unhappy symptoms; but this was a great mistake, one that is made by many laboring under like conditions. Instead of marriage, such parties should seek as a remedy the advice and treatment of the intelligent, scientific physician, one honest and reliable, making these cases a special study. Unfortunately for the community, the advertising quacks have had the majority of these delicate and all-important cases as their greatest source of revenue. Upon passing the sound I found the urethra very tender, with a spasmodic stricture located at or near the prostatic gland. The passage of the sound was continued twice a week to dilate the urethra and to lessen its irritability. During the emission of semen, and just previous to that act, he observed a peculiar sensation or warning similar to the aura of epilepsy. Hence I placed him upon the bromides and atropine at night, and administered the nitroglycerine pills (1-50 gr. each), one three times a day, and ordered warm baths and careful diet. The effect of this treatment was to arrest his trouble, and to gradually restore him to physical and mental health. After this treatment had been continued for several months, I placed him upon tonic treatment, consisting of the fluid extract of damiana, belladonna, nux vomica and tincture of cinchona compound, with occasional applications of electricity to the spine. This, together with a select diet, added greatly to his vigor and procreative powers. All unnatural discharges have long since ceased, and his wife, several months advanced in pregnancy.

The number of cases throughout the land is legion, and ever will be until our communities are taught to value scientific and special treatment.

*Neurasthenia.*—Mr. D., aged twenty-five, a student at law, who also performed the duties of a clerk in an office controlling a large practice. His studies and duties proved too arduous an undertaking, and soon broke him down mentally and physically, being of a nervous and ambitious disposition. He suffered greatly from nervous dyspepsia and general nervous exhaustion. He lost flesh, lost sleep, and was tremulous and depressed, and suffered frequent seminal losses night and day. Upon examining the urethra, it was found to be irritable, with a continuous weeping discharge. No stricture was found. The penis was small, flabby and cold. I ordered him a vacation and administered atropine with bromides until the nervous irritation had subsided. I then gave a tonic consisting of liquor sedans and saw palmette during the day, with doses of pichi and hyoscyamus at bedtime, as required, making applications of the Faradic current locally and generally every few days. This treatment was kept up during the summer vacation, until late in the autumn, when he returned to his vocation, generally better, and greatly restored in his nervous system. With better sleep, good appetite, and genital functions normal, the use of electricity was continued a term longer when he left my care, with the advice to be more moderate in all things.

*Neurosis of Genitalia with Nervous Paralysis.*—Mr. K., aged thirty-three, was referred to me because of suffering from general nervous prostration. He is tall, athletic and active; he had lately lost his

color and vivacity; and had accuired an unaccountable dread of persons and places. He was almost a monomaniac in the fear of on-coming "loss of manhood," or paralysis of his procreative powers. Upon examination I found it was his custom to endure prolonged and arduous mental work, neglecting the regularity of sleep, diet and recreation. He had a fine constitution and physicial development. His genito-urinary organs were intact and well-developed, and proved readily amenable to treatment by proper hygiene, occasional administrations of electricity, and a tonic consisting of coca, sandal and vanilla. A few months of such treatment fully restored him in every particular. His physician deemed his mental phenomena of an abnormal and perhaps dangerous character, hence he referred him to me. All his unpleasant symptoms passed away as he gradually improved, though a case neglected long enough undoubtedly might have ended in some permanent pathological lesion.

*Impotency due to Excessive Use of Tobacco.*—Mr. G., aged 31, married, was referred to me as a case of impotency. I found him a hale man, well developed mentally and physically. His muscles were hard and elastic, and he was able to endure great physical strain. All of his organs were well developed—especially those of the genito-urinary system. After a thorough inquiry, I found that he was excessive in the use of tobacco, chewing and smoking to an alarming extent, and at times was in the habit of taking alcoholics too freely, all of which I forbade. I ordered for him a moderate diet and pills of damiana and nux vomica; also the daily application of the Faradic stimulus to the cord and genito-urinary appendages. He was to abstain from all genital exercises. He continued under treatment for several months, with most excellent results.

Tobacco and whiskey are, in my opinion, frequent inhibitors of the sexual act.

Case 92—*Inertia of Uterus.*—A young married lady, aged 22, from a fright or shock, suffered abortion during her first pregnancy. After this her menses were scant and irregular, with failing health for several years. She did not become pregnant during this time. After a careful examination, I diagnosticated a neurasthenic condition with consequent inertia of the genito-urinary organs. I ordered generous diet and hygiene, gentle exercise, and administered fluid extracts of Damiana and Haw three or four times daily, commencing with small doses and gradually increasing. After a few months the menses became more regular and pronounced. With general improvement of health and spirits, at the end of the third month of treatment she became enciente, and went through a regular term with a happy delivery.

Case 163—*Impotency.*—A gentleman of 36 years, of delicate frame, constantly complained of feeble digestion, irregular bowels and constipation. His complexion is sallow, he sleeps badly, his habits are sedentary, and he is given to literary affairs. Has been married several years without issue. His wife is buxom, active and regular. Upon examination I found his organs rather small, with the power of incomplete erection only. His semen under the glass exhibited but few evidences of life. I ordered a more active life, less study, regular hours and diet. Placed him on fluid extracts of Damiana and Stylosanthus, and after six months careful management he was greatly restored.

In cases of impotence from masturbation, accompanied by spermatorrhœa, we find morbid changes in the vesicular seminales, ejaculatory duts, bulbous portion of the urethra and prostate gland. Such cases frequently require surgical and special treatment; and in detecting and locating these lesions I have found nothing equal to photographing them by the sound in the galvanic connection, as introduced.

**Mixed.**

She had read the advertisements
In the papers o'er and o'er,
But had gotten somewhat muddled
As to what each thing was for.

So when she had a bilious turn,
She took some Pyle's Pearline;
She scrubbed the floor with Sozodont,
But could not get it clean.

And for a torpid liver
She took Sapolio,
And put Castoria in the cake;
She got them muddled so.—Jay Kaye.

# SOCIETY REPORTS.

## THE LOUISVILLE MEDICO-CHIRURGICAL SOCIETY.

*Meeting October 13, 1893.*

DR. T. L. MCDERMOTT, President in the Chair.

### MALIGNANT DISEASE OF ANTRUM—OPERATION.

DR. W. L. RODMAN: I have a specimen here which does not seem to be a bone but it is, nevertheless, the remains of a malar bone, the seat of malignant disease. It was removed to-day from a patient fifty-two years of age, female, living in Indiana, who came here with a well-marked tumor of the antrum which proved to be a malignant growth. The direction of this tumor was upward and outward instead of internally, the direction in which these tumors usually grow, making the malar bone very prominent. The operation was performed yesterday, and I was assisted by Drs. Dugan and Tuley. I cut immediately down upon the malar bone and this is the remains of it. It does not feel like bone at all, feels more like fibrous tissue. After removing the end of the zygomatic process, which was also diseased, the antrum was exposed and we removed with the curette a large growth sarcomatous in nature, I take it. The antrum was then thoroughly cauterized with zinc chloride. Hemorrhage was quite profuse but easily controled by tamponing with gauze. The patient stood the operation very well; I believe when she went on the table the pulse was 116 and at the close of the operation the pulse was 120. What is a little remarkable is the fact that this evening her pulse is only 68 and good volume.

I was then led to do this operation rather than the more standard one of excision of the upper jaw, on account of the fact that I think recent investigations have shown rather clearly that the old operation of excision of the superior maxillary bone is perhaps not a justifiable operation. Butlin, in reviewing 108 operations removing the upper jaw, states that the immediate mortality is rather more than 30 per cent., that of this 108 cases only five passed the three year limit which can be looked upon as a cure. There is very little, I think, to promise patients after excision of the upper jaw, because nearly all of them return very speedily, and, in view of the great mortality, other operations should be done if possible. The tumors affecting the upper jaw are in a very large percentage of cases malignant. In a paper read two years ago before the State (Kentucky) Society held at Louisville, I went over the subject pretty carefully and found that 76,3-10 per cent, are malignant, the larger proportion of them being sarcomatous rather than carcinomatous, and 23,7-10 per cent. benign. Of these rather more than 8 per cent. are cystic, the balance fibromas, osteomas and enchondromas.

In the case reported by me to-night, the tumor has not been subjected to a microscopical examination, but from its macroscopic appearance there is very little doubt in my own mind as to its being sarcomatous in nature.

#### DISCUSSION.

DR. S. G. DABNEY: I would like to ask whether in early stages of these growths within the antrum, the so-called Heryng test is used for illumination within the mouth. My own experience with it in diagnosticating suppuration of the antrum has been favorable. I believe if we will observe just beneath the eye, we will find in diseases of the antrum the affected side is rather darker than the other, even when there is no difference in transparency lower down in the cheek. My recollection is that this test was first used for differentiation of tumors of the antrum, to detect the solid from cystic tumors. Is its use satisfactory in making the diagnosis of tumors in the antrum?

DR. D. T. SMITH: I would like to ask the justification of any operation at all in this situation. A suppurative condition I judge could be ascertained and differentiated from others, which would naturally require operation or opening at all events. On the other hand, if operation is demanded, I should think complete excision of the jaw rather than partial excision would be preferable and promise more for the patient in the way of permanent results.

DR. W. L. RODMAN: Answering Dr. Dabney's question I have never seen the test used; it seems to me it would be a valuable means of diagnosis. It would possibly enable us to make a more accurate diagnosis in these cases, because it would show if the tumor had encroached upon the nares, as these growths nsually do.

The objection to complete excision of the upper jaw is that the primary mortality is more than 30 per cent., and if you cannot promise very decided benefits from an operation that gives so high a mortality, then it occurs to me that the operation is not justifiable. I was led to give this woman the bene-

fit of surgery particularly on the account of the fact that she was suffering great pain from pressure. I believe by the removal of the diseased bone and the thorough curettment of the antrum, the patient's life will be prolonged, and the mortality of an operation such as was done in this case I do not think is at all considerable.

DR. W. C. DUGAN (Visiting): There is another feature in this case that struck me as being very peculiar, and that is there was no encroachment upon the nares. The patient was able to breathe through the affected side without trouble, and in discussing the case at the last meeting of the Surgical Society, where the patient was shown, this fact was mentioned. It struck me then that if there ever was a favorable case for operation this was one. We were very much surprised at the operation to-day to find that the growth had extended from the malar bone to the upper portion of the antrum, rather than from the antrum outwardly. I agree with Dr. Rodman that the patient was relieved of a great deal of pain. She was unable to open her mouth before the operation, and I am quite sure she will be able to do so now, for in my opinion the pain was largely due to the tumor being beneath the masseter muscle.

DR. W. L. RODMAN: In reporting the case I neglected to mention the fact that this patient was unable to open her mouth before the operation, but as the masseter muscle was cut I am certain she will be able to do so now and masticate her food.

DR. W. C. DUGAN: I am very much surprised at the high mortality of this operation. I have had several similar operations lately without any immediate fatality, but I am like Dr. Smith—it is rather doubtful in my own mind as to whether this operation should not have been total excisions as I feel confident that we could have gotten all the growth out.

DR. W. L. RODMAN: The literature of the subject is rather conflicting: Gross states that he operated upon twelve of these cases, excising the jaw as many times, without a single death, and makes the most extraordinary statement that the operation is free from danger. Yet Butlin, in a very careful review of 108 cases, states that the primary mortality is more than thirty per cent., and only five of them lived past the three years limit, which is ordinarily regarded as the proper time to suppose that a cure has been effected. I would pay a great deal more attention to Butlin's statistics than those compiled by anybody else, as we know that his life work has been devoted to malignant disease, and he has shown most extraordinary energy in following up his cases.

#### DISCUSSION

of Dr. S. G. Dabney's paper. See page 88.

DR. J. M. RAY: One point that impressed me concerning the obstruction of the canal from wax, is the habit some people have of having recurrent attacks of accumulations of wax in the ear. I have in mind a man from whose external auditory canal I have removed twice a year for the last four years enormous accumulations of wax. His hearing powers are perfectly normal, and careful examination reveals no disease of the middle ear. Again, its proneness to occur in warm weather.

With reference to inflammation of the external auditory canal: The majority, I see, involve the outer part of the canal and are furuncular. I have seen several cases where incisions have given relief, and a few in which they seemed to give no relief whatever. I think Roosa teaches that incisions as a rule give very little relief to inflammations of the external auditory canal. One of the best means I have found to give relief is to allow the patient to lie down and pour hot water into the external canal, keeping it filled with hot water. I do not remember to have seen a case involving the mastoid periosteum as a result of external ear inflammation. There is no doubt but in furuncular inflammations of the canal, there is some general systemic condition that underlies it.

I have had under observation during the present summer a young man who has had a most obstinate attack of recurring furuncular inflammation of the external auditory canal. I saw him in four or five attacks; he suffered great pain, and at last I advised him to take a vacation and go to the country. He went up in Illinois somewhere, remaining two or three weeks, and has not had any inflammation of the canal since his return. While he was under my treatment I gave him tonics—Fowler's Solution, etc.—which seemed to have no effect. His trip to the country, getting fresh air and country food, seemed to produce a change in his condition for the better, and since his return to the city has had no recurrence of ear trouble.

DR. T. L. MCDERMOTT: In the last week I remember reading a pamphlet setting forth the fact that poultices applied externally had very little effect upon internal inflammations of the ear. In this article the author advocated the pouring of hot water current into the ear, which would in the majority of cases afford relief. It struck me as a very wise procedure, and Dr. Ray's remarks recall it.

I have under observation now a little boy, three or four years of age, who has fever, and apparently at first suffered from some bowel trouble; pain quite severe, but could not be definitely located, owing to his age. On the second night he complained of severe pain in the ear, lasting through the night. His head was kept in one position, and this symptom was so persistent as to suggest

torticollis. This morning he still complained of pain located in the ear. Temperature yesterday 103° F., this morning 102½° F. He has had a typical clonic spasm from the history elicited from the family. I believe that this child has some trouble in the middle ear not yet fully developed, which is causing the elevation of temperature. Since I have seen the case there has been no contraction of the muscles which we would expect to find in torticollis, and no tenderness anywhere. There is no contraction or dilatation of the pupils, no cough, no sore throat, no diarrhœa, and nothing indicating disease, except this obscure ear trouble.

DR. J. A. LARRABEE: I believe that the child is suffering from rheumatism, a disease frequently overlooked in childhood.

DR. J. M. RAY: There may be some middle ear trouble, but mastoid tenderness may occur from the drawing effect upon the sterno-cleido-mastoid muscle.

DR. T. L. MCDERMOTT: It is one of three things, external ear trouble, rheumatism or developing cerebro-spinal meningitis, the symptoms are not localized.

DR. S. G. DABNEY: The discussion has taken rather wider turn than the character of the paper called for. There is no doubt that hot water allowed to run for a long time is one of the best methods of treating inflammations of the external auditory canal, because the hot water reaches the drum membrane whereas poultices must be an inch more or less removed from it. I believe that the Fountain syringe is the most valuable for this purpose. Parents and nurses are very apt to use the Piston syringe, which is too forcible and adds to the irritation already existing.

As regards complication of the mastoid in inflammation of the canal: I have encountered this in two or three cases in children, but the inflammation was always confined to the periosteum over the mastoid process and did not involve the cells of the bone.

---

TWO CASES OF FOREIGN BODY IN THE EAR.

DR. J. M. RAY: I will report two cases bearing somewhat upon the paper read by Dr. Dabney—cases of foreign body in the external ear. I recently had under observation two cases in which insects had gotten into the antrum ear and remaining there for some time. One case is now under observation: The patient is a young lady who while riding on a street car at night suddenly felt something enter her ear. She went home and poured something in her ear that she thought would kill the insect and the next day consulted a physician, who said there was nothing in the ear. For six weeks she had no trouble then she began to have violent earache. She suffered several nights before consulting me. Upon examination I found the canal blocked by something, I was unable to make out the nature of, she did not at first give me the history of the insect. She said it had been so long she had about forgotten the occurrence. I then began to syringe the ear and removed several pieces of black material, and upon further syringing and with a dull curette I picked out a headless insect as large as a bean; after I had syringed this all out, and examined again I could still see something lying at the bottom of the canal close to the drum membrane. The canal was so tender and inflamed that I could do nothing further toward removal, so advised the use of hot water injections. The ear suppurated in a day or two, and she went through a case of suppuration of the middle ear. After that subsided I could still see something in the canal, and with a strong solution of cocaine allowing the patient to lie on her side for some time until anæsthesia was produced I passed a dull curette behind the body and picked out the head of the insect as large as a shot and very hard, which had remained there through the suppuration and for six weeks previously.

No. 2.—The other case, a gentleman stepping off the street car one night felt something fly into his ear, and suddenly became so dizzy that he could with difficulty walk. He went home and poured oil in his ear to kill the insect. He remained very dizzy during the next day. The second day he consulted me and upon examination I discovered an insect lying in the canal. It was removed by syringing, when the patient again became very dizzy and had to lie down for a few minutes. The insect had dropped down against the drum membrane. The peculiar feature in the case is the intense dizziness caused.

---

OPHTHALMIA NEONATORUM.

DR. T. L. MCDERMOTT: A lady called at my office with a little child evidently suffering from ophthalmia neonatorum. As the case was not in my line I advised that she consult an occulist. She said another physician attended her during delivery and had been treating the child's eyes since. Of course what the nature of his treatment was, or how often he visited the child, I do not know. I sent her to Dr. Ray, and I want to ask the doctor one question in regard to the subject; whether under proper treatment immediately after birth the trouble in the majority of these cases could not be averted.

DISCUSSION.

DR. M. RAY: The case referred to by Dr. McDermott belongs to an unfortunate class, the corneæ are perforated, one eye collapsed; the other seriously affected, but may retain a little sight. Ordinarily cases of ophthalmia neonatorum come on about four days after

birth and run a very rapid and often destructive course. I do not know that I can say very much about the case in question. The visiting physician evidently did not impress upon the mother the importance of the trouble, as she had not kept the eye free from pus.

At the meeting of the American Ophthalmological Society the past summer quite an extensive discussion was carried on with reference to the responsibility of the doctor in cases of ophthalmia neonatorum, and it was the concensus of opinion that cases were sometimes lost, and it did not make any difference who treated them or the method of treatment. The doctor should not be held accountable for an eye destroyed in ophthalmia neonatorum. There is one class of cases that I believe almost invariably go on to destruction, and that is in a premature child. I never saw a case of ophthalmia neonatorum in a child of seven or eight months but the eyes were seriously injured. I had a case of this nature during the summer. I saw the child three or four days after the eyes became involved aud at that time one cornea had become infiltrated; the other eye quickly became involved, and in a short time was also destroyed. The case referred to by Dr. McDermott was a seven-months child.

I believe that such children are peculiarly prone to this affection and suffer more severely from the effects than those born at full term. It is probably due to the fact that the resisting powers are greater in a child fully matured than one prematurely born.

DR. F. WILSON: What is the most successful plan of treatment?

DR. J. M. RAY: Perfect cleanliness is the best treatment I know of. I think the best local application is nitrate of silver; this to be used by some one who knows exactly how to do it. If due care is exercised I believe that a ten to twenty or even forty grains to the ounce solution of nitrate of silver can be employed with benefit. I remember a case I had several years ago in which I used a forty grain solution of nitrate of silver, stopping a purulent ophthalmia in one eye of a child, the other eye being seriously affected at the time. By thoroughly cleansing the conjunctiva and applying nitrate of silver it ran a very mild course and in less than a week the eye had perfectly recovered. The other eye in which the trouble had existed for a greater length of time, was two or three weeks recovering and with a superficial corneal abrasion. I believe the time is not far distant when all obstetricians will recognize the importance of preventive measures in these cases. I am sure such methods as those of Crede will prevent many cases. The Louisville City Hospital has during my service always been unfortunate in having a number of such cases.

DR. J. A. LARRABEE: In treating ophthalmia neonatorum I do not think it is safe to intrust the cleansing of the eye to anyone except the physician himself. I have had some nurses of large experience, and even then it is very risky the first twenty-four hours of the treatment to intrust them with the cleansing of the eye, giving the most minute directions. It is a very difficult thing to do I find. The eye shuts up like a mollusc and the more pus there is the tighter it is closed. It will hold a teaspoonful of pus. The lids come out to a level with the supercillary ridge remaining there swollen. I have had a nurse tell me there was nothing in the eye, when upon a careful personal examination a large quantity of pus has been found. Therefore, as has already been stated, I do not think it is safe for any physician to intrust this work to nurses, even trained nurses. I have used nitrate of silver by preference, getting it in just as soon as I could. I have more confidence in it than in any other agent outside of cleanliness.

DR. D. T. SMITH: If there is one thing that has puzzled me more than anything else in medicine, it has been to make up my mind as to the proper treatment for ophthalmia neonatorum, from reading books. They generally recommend nitrate of silver, but scarcely two of them agree as to the strength that should be used. Some insist that it should be very weak, others insist that very strong solutions are desirable. I am very doubtful in the average case whether nitrate of silver is required at all. I believe that Dr. Ray has solved the whole problem in saying that absolute cleanliness is the best treatment. The child's lid should be thoroughly cleaned every half hour with water about as salt as the normal tears, or at least every hour, all the pus being removed by gently pressing the under lid, and the lids never be permitted to stick together. I positively enjoin that somebody be up with the child night and day. Probably the most of us have suffered from ophthalmia at times, and know how painful a small particle of pus is under the lid. By gently pressing the lid and passing the finger over it this can almost always be removed. I have had such satisfactory results in the treatment of this affection simply using salt water, keeping the eyes perfectly clean, that I feel like using nothing else. I have employed nitrate of silver in some cases trying to follow the teaching of the latest books, then I would read the work of another author advocating a different strength of the solution, until I have found there is such a great variation that I have about come to the conclusion that any treatment which admits of such variation would

admit of being dispensed with altogether. As a rule I do not believe we visit these patients with sufficient frequency, leaving the treatment too much in the hands of the attendants. We should see them often, and insist that some one be present at all times to keep the eyes clean and taking pains to see that our instructions are understood.

DR, J. W. IRWIN: My views are a good deal in accord with Dr. Smith's in regard to the treatment of ophthalmia neonatorum. I have seen a number of cases of this disease, which come on one, two, three or four days after birth, and I have never seen a child to lose an eye or have a perforation of the cornea. Furthermore, in no instance have I had to apply nitrate of silver solution in the treatment of these affections. Had they been of gonorrhœal origin, it is possible I would not have gotten off so well. Therefore I am inclined to the opinion, so far as my experience goes, that this disease even in the majority of cases is not of gonorrhœal origin. The treatment in the cases I have seen was simple. I have had the eyes washed out clean with a weak solution of borax and water, and subsequently with one-fourth grain of sulphate of zinc to the ounce of water instilled into the eye with a dropper glass six or eight times a day. In a few instances, where the suppuration was very profuse and where it was very hard to control, I had the nurse to apply a solution of bichloride of mercury, one grain to one ounce of water, with a camel's-hair pencil once a day only. Two or three applications of this solution sufficed to put an end to the disease. This I believe to be the best means of all for controlling these disorders. When I was a student I was taught that sixty grains to the ounce nitrate of silver solution would be required in these cases. I have read in books that it takes anywhere from five to fifty grains to make a solution sufficiently strong to be effective. I have never yet had to apply to the eyes of a young child nitrate of silver in any form.

DR. S. G. DABNEY: I would like to say something in regard to both cases reported by Dr. Ray, as they are both of extreme interest. Concerning foreign bodies in the ear: I wanted to include something about this in my paper, but did not do so. A mistake that is very often made in removing foreign bodies from the ear, is to use instruments. Sir William Dalby goes so far as to say that injury is far more often done to the ear by attempted removal of foreign bodies than by the foreign body itself. In almost every case the syringe alone is sufficient for the removal of foreign bodies from the ear; and forceps, spoon, or other instrument, are both needless, and, except in expert hands, dangerous. In one class of cases the syringe should not be used, namely, when the substance is one that swells when in contact with water—peas, beans, etc. I remember one case where a child was brought to me who had gotten a bean in the ear; it had been syringed several times, but the bean had slipped deep in the canal and was swollen from the use of water in attempts to remove it, and the canal itself was already inflamed and narrowed. In that case it was necessary to give chloroform before the bean could be gotten out. It was easily removed, and in a day or two the swelling passed away. Cases of this kind, however, are very exceptional. Another case was a child who had gotten a grain of corn in the ear; the family physician had made several attempts to remove it by injections of water, but had not succeeded. The grain had been in the canal for some time, and the water had caused it to swell, so that it could not be removed except by taking it out in pieces. This is nearly always the case where the grain is not removed by the first injection of water.

As regards live insects in the ear: Patients very often go to their doctor and say they have a little bug in their ear as they can hear it. I remember one case where a small insect had gotten in the ear of a patient, and was still alive when I saw it many hours afterward, and was fluttering, but usually the insect soon dies after it gets in the ear.

I was particularly interested in the discussion of ophthalmia neonatorum. Just before the society was called to order I mentioned a case to Dr. Tuley which I saw for the first time to-day and found with a deep ulceration of the cornea. The child is now about two weeks old; the accoucheur dismissed both the mother and child six days ago, and I suppose the child was then doing well and the eyes improving. Since that time, however, the olphthalmia has not improved and now the condition of one eye is critical.

As regards the treatment of ophthalmia neonatorum—there can be no question but absolute cleanliness is the key-note to the whole situation. This carried out with care is usually alone sufficient for a cure but to hasten the cure there is nothing equal to nitrate of silver solution, and I am a little surprised that Dr. Smith should have found such diversity of opinion among writers as to the strength to be used. For ordinary purposes a two per cent. solution, ten grains to the ounce should be applied. In a report from the Presbyterian Eye and Ear Hospital of Baltimore sent out last June, Chisolm says the old plan of treatment in this disease still holds good; that is a four per cent. solution of boric acid used by the nurse for cleansing the eye as often as matter accumulates and the daily application of nitrate of silver by

the physician, usually ten grains to the ounce. This is the course of treatment I usually follow.

I was particularly interested in the point made by Dr. Ray in regard to suppuration of the cornea being so much more frequent in children who were born prematurely. This is in accord with the well known fact that disease of the cornea is most severe in debilitated subjects, even in adults, the corneal condition is often an index to the general health.

DR. H. A. COTTELL: The subjects under discussion are exceedingly interesting, not only to the specialist, but to the general practitioner. Concerning the matter of foreign bodies in the ear: I believe every general practitioner should keep an ear speculum and mirror and know enough about the anatomy of the ear to make an intelligent examination, not simply turn the patient around to the window as so many of them do and look into the ear without speculum or glass. He does not see to the bottom of the canal by that means, and many patients are allowed to go away with foreign bodies in the ear. I keep a set of ear specula and many times I have removed foreign bodies from the ear. I had the honor of removing an insect from the ear of a distinguished surgeon the other day. He came into my office stating that he "knew he had a bug in his ear, that he could hear it buzz," asking me to get it out. I took the speculum and glass, secured an illumination and detected a little brown object in the canal which proved to be a very small insect, (of the beetle order, I judge) and alive. It was very easily removed with a syringe and some water.

I have seen accumulations of wax in the ear, as you all have, which practically amounts to the same thing as a foreign body, and sometimes sets up a considerable trouble of a reflex character. But I want to have the subject of reflexes due to irritation of the external ear brought up some time for discussion.

A word or two in regard to ophthalmia neonatorum: Of course all doctors see this disease, and although I have never had a severe case to develope in my practice, I have had one or two pretty severe ones brought to me. One I remember came from another city; the eyes looked to me as if they would be destroyed. I did not have the temerity to attempt to treat the case. I sent the case to the Infirmary and asked Dr. Cheatham to see it. I remember he put the child in charge of a trained nurse and was very specific in his directions to have the eyes cleansed with considerable frequency, and that he used a solution of nitrate of silver of different degrees of strength, beginning with a weaker and going up to a stronger solution. In a few days the child was well. That child would certainly have lost its eyes if it had gone on under the treatment the country doctor was giving it.

Concerning the question of using peroxide of hydrogen in the treatment of purulent conjunctivitis: Peroxide of hydrogen ought to be the ideal remedy for that trouble, and I think the reason it is not used is that it is too irritating, owing to the acid it contains. Now there is no peroxide of hydrogen made that does not contain acid. When the Oakland Company's came out some time ago, it was received with a great deal of enthusiasm because it was only slightly acid. I took a sample bottle of the Oakland Company's and made some experiments with it, and while it was very much less acidulous than the other preparations, it still contains quite an excess of acid and is bound to be irritating. If used in the eye it would have to be diluted to such a degree that it would not have any marked effect. If chemists can make a peroxide of hydrogen which shall be neutral, they will put in our hands a very valuable agent.

DR. H. E. TULEY (visiting): During my term of service at the Sloane Maternity Hospital in New York there were 202 births; the Credé method was observed in every case, two drops of two per cent. solution of nitrate of silver being instilled into each eye immediately after birth, and there was not a single case of ophthalmia neonatorum during that time. This method is followed in every case, after birth, and I do not think they have had a case of ophthalmia neonatorum there in a long time—I know they have had none in the last thousand births.

DR. P. F. BARBOUR (visiting): While I was in the City Hospital here, we adopted a method of preventing ophthalmia neonatorum which succeeded in every case. This method was to cleanse thoroughly the child's hands with boric acid solution. It seems to me that they should receive attention. One of the first actions on the part of a child is to rub its hands into the eyes. I believe if the hands as well as the eyes are kept cleansed with some mild antiseptic, there will be much less of this trouble.

DR. T. L. MCDERMONT: In all the women we deliver in the course of many years, it is possible that we might not have a case of ophthalmia neonatorum, then again it might occur very frequently. Of course there are reasons why there should be more cases in hospital practice owing to the class of patients presenting at such an institution for delivery. Gonorrhœal infection is much more liable to be encountered there than in private practice. Our discussions of matters of this kind will bring them to the attention of other and younger physicians and I believe good will

result from greater care exercised in an endeavor by proper treatment to prevent trouble in this direction.

DISCUSSION

of DR. T. H. Stuckys' paper. See page (91).

DR. T. L. MCDERMOTT: I had an experience of similar character at the Springs this summer: A man was suffering from alcoholism and I prescribed paraldehyde in small doses. The effect was so pleasing that he consumed the whole vial, six ounces, in one day without any perceptibly bad effect. In another case at Seelbach's Hotel, in ordinary doses, it produced violent heart symptoms with evidence of poisoning. Here are two cases in which the action of this drug was directly opposite. I remember prescribing paraldehyde to another patient who was suffering from alcoholism. The druggist two weeks afterward called my attention to the fact that this man was getting from four to six ounces of paraldehyde per day, and asked if it was my wish to have it continued. I of course instructed that he be sold no more, as I did not intend for it to be continued. That case was similar to the one reported by Dr. Stucky—the man was going about the Springs taking four to six ounces of paraldehyde a day instead of whisky.

DR. J. W. IRWIN: What were the character of the heart symptoms?

DR. T. L. MCDERMOTT: Palpitation; respiration was also depressed. I understand that this patient died three or four months afterward in New Orleans, but I did not ascertain the cause of death.

DR. J. W. IRWIN: I was greatly interested in Dr. Stucky's report; it comes right within the sphere of my own observations perhaps more than any other. I have had some experience in treating persons suffering from insomnia in its various forms, and have prescribed paraldehyde a number of times. I recall one case where a patient had been taking paraldehyde for nine months every night. The dose has not been increased—one-half to one ounce every night. When he first began the use of paraldehyde it had a stimulating effect, as though he had been taking alcohol; but this effect did not last long. He then began to suffer from suffusion of the eyes with redness of the conjunctivæ and dilatation of the pupils, which would last for one or two hours after getting up in the morning. Soon after going out into the open air the pupils become normal but the suffusion of the eyes continue. He suffers from a little redness or flushing of the face; at times he shows evidence of uncertainty of gait, and in walking across the floor he staggers. He does not plant his feet on the floor as a healthy man should ordinarily do. There is no other change in his condition; it has not affected the heart, nor does it today.

No. 2.—Another gentlemen came under my observation who had spent a year or two abroad and had been taking paraldehyde for insomnia. He used Flexner's preparation in doses of half ounce at night causing sleep of six to eight hours. At the time I saw him he was suffering from a feeling of constriction about the stomach, as though a band had been tied around him. He had not been using alcohol or anything that would have put the stomnch out of order and he thought the paraldehyde might have been the cause of his trouble. I had the paraldehyde stopped had the urine examined and found a trace of albumen with hyaline casts, slightly granulated. This was the report of the chemist. After two weeks without paralydehyde, the constriction had passed away, the trace of albumen had disappeared, and so did the casts in the urine. He sleeps now without paraldehyde, takes no medicine of any kind and I believe in this case it was only imagination that he could not sleep.

I have several other cases who are using paraldehyde but these are the most striking. The largest dose I have to prescribe in any case was one ounce of Flexner's Elixir. One gentleman is taking pure paraldehyde and he thinks it is the greatest remedy in the world for insomnia. The only bad effects I have observed after the use of paraldehyde are that in one case it produced suffusion of the conjunctivæ, flushing of the face in the morning, dilitation of the pupils and a slight conjunctivitis. In a few instances in acute disease I have prescribed paraldehyde in large doses to cause sleep; I have given as much as six ounces in one night to one patient. This caused an acceleration of the pulse from ninety or one hundred to one hundred and twenty and the patient awaking from sleep rather weak and feverish. These are about the only untoward symptoms I have observed so far.

---

THE MARK OF THE BEAST.—Forrester—"Did you see me making a fuss over that baby?"

Lancaster—"Yes. How much do you owe him?"—*Truth.*

---

CAUSE FOR THANKS. — Teacher — Johnny, can you tell me anything you have to be thankful for in the past year?"

Johnny (without hesitation)—"Yessur."

Teacher—"Well, Johnny, what is it?"

Johnny—"Why, when you broke your arm you couldn't lick us for two months."—*Life.*

# THE LIBRARY TABLE.

## BOOK REVIEWS.

*A Practical Treatise on Materia Medica and Therapeutics.* By Roberts Bartholow, M A., M. D. LL.D. Eighth Edition, Revised and Enlarged. New York: D. Appleton & Co., 1893.

The decennial revision of the United States Pharmacopœia involves so many changes in remedies and formulæ that a treatise on Materia Medica must, of necessity, be newly edited to make it conform to the only official standard. Formulæ have been changed as required by the Pharmacopœia, and a list of remedies, many of which have only recently appeared, have been added. An account, more or less complete, of the various new synthetical products will be here found. So important are their attributes, so largely have they come into use, and so great is the demand for true information regarding them, that a text-book would be considered wanting in thoroughness and completeness if it contained no reference to the more important of them.

We know of no work on Materia Medica and Therapeutics that we could more unhesitatingly recommend than this one, and we express the belief that this new edition will prove still more worthy of the remarkable favor which the work has enjoyed from its first appearance.

*An Outline of the Embryology of the Eye.* With illustrations from original Pen Drawings by the Author. By Ward A. Holden, A. M., M. D., New York. G. P. Putnam's Sons.

The research was carried out in the New York Ophthalmic and Aural Institute, and is based upon the examination of a great number of specimens. The chick-embryos were obtained by incubation, were hardened in Kleinenberg's or Muller's fluid, and stained with carmine and hæmatoxylin-eosin. The pig-embryos were obtained fresh and hardened in Muller's fluid after decalcifying, when necessary, with phloroglucin or hydrochloric acid mixtures, and the sections were stained mostly with hæmatoxylin-eosin. The study received The Cartwright Prize Essay for 1893.

The author presents a clear and comprehensive description of the development of the eye giving first a brief and purely schematic sketch of the processes which take place, explaining them with diagrams. He next gives an accurate histological description of the various parts of the eye in their successive phases of development, and illustrates these descriptions with careful drawings from actual preparations.

*The Child, Physically and Mentally—Advice of a Mother, According to the Teaching and Experience of Hygienic Science. Guide for Mothers and Educators.* By Bertha Meyer. Translated by Friederike Salomon Revised by A. R. Aldrich, New York; M. L. Holbrook Co.

Thirteen years have elapsed since Bertha Meyer's book "From the Cradle to the School" was translated and offered to the English speaking public. "The Child" which we now have before us, shows the same careful hand, the same endeavor to comfort, and to educate; and if the precepts here laid down be observed, blessing and health to children are bound to follow.

Many helpful suggestions are made. Throughout the entire book great stress is laid upon hygienic rules for attaining physical and mental health and educating body and mind harmoniously.

The 155 pages are deserving of a careful study.

*Surgery.* By Bern B. Gallaudet, M. D., Demonstrator of Anatomy and Clinical Lecturer on Surgery, College of Physicians and Surgeons, New York, Visiting Surgeon, Bellevue Hospital, New York, and Charles N. Dixon-Jones, M. D., Assistant Surgeon, Out-Patient Department Presbyterian Hospital, New York. Being the final volume of "The Students Quiz Series." Edited by Bern B. Gallaudet, M. D. Duodecimo, 291 pages, 149 illustrations. Cloth, $1.75. Philadelphia. Lea Brothers & Co., 1893.

The author has endeavored to present this book, not as a compend or digest of surgery, but rather as one which would *explain*. Among the principles of surgery, Inflammation is one, the clear comprehension of which seems attended with peculiar difficulties. This book elucidates this subject fully. But as it is a fact that the *varieties* of inflammation *themselves* are recognized as being either "specific" or "non-specific," and that putrefaction is a process distinct from inflammation, the author deemed it best to avoid all discussion, and to classify the bacteria as *causes* in the same way in which their effects—i. e., inflammation and putrefaction—are classified.

In addition to inflammation, three other subjects have received especial attention. These subjects are: Tumors and Cysts, Brain Surgery, and Abdominal Surgery.

*Essentials of Minor Surgery, Bandaging, and Venereal Diseases.* Arranged in the form of Questions and Answers. Prepared especially for Students of Medicine. By Edward Martin, A. M., M. D. Second Edition, Revised and Enlarged. 78 Illustrations. Philadelphia: W. B. Saunders, 1893.

This little volume, being No. 12 of Saunders's Question-Compends, has been thoroughly revised and brought up to the present standard of surgical practice. A large number of illustrations have been redrawn and engraved. Many of the omissions made in the first volume have received careful attention in this edition.

*New Truths in Ophthalmology* as developed by G. C. Savage, M. D. Thirty-two Illustrations. Publishing House of the M. E. Church South, Nashville, Tenn. 1893.

The author states that "In presenting this little volume to ophthalmologists who read," he "feels that he is doing them a service that will be appreciated." The book is considered under three parts:

Part I. New Truths in Ophthalmology. Part II. Contributions to Old Studies. Part III. Operations.

For all that is new or of any value in this little volume, the author might have satisfied his literary ambitions with a few contributions to some of our medical journals.

---

*Essentials of Bacteriology.* Being a Concise and Systematic Introduction to the study of Micro-organisms. For the use of Students and Practitioners. By M. V. Ball, M. D. With eighty-one illustrations, some in colors and Fine Plates. Philadelphia: W. B. Saunders, 1893.

In this little book of some 200 pages, Bacteriology is considered under two heads, General Considerations and Technique, and special Bacteriology, together with an elaborate appendix.

That this value should so soon reached its second edition, confirms our views of its success already expressed in the review of the first edition.

*The Physician's Visiting List for* 1894. Forty-third year of its publication. Philadelphia: P. Blakiston, Son & Co.

What better evidence of success is wanting than the fact that this Visiting List has reached its forty-third year?

It contains sections on New Remedies, Incompatibilities, Poisons and Antidotes, Disinfectants, Examinations of Urine, Differential Diagnosis and Treatment of the Simpler Diseases of the Eye, Table of Eruptive Fevers, Asphyxia and Apnœa, a New Complete Table for Calculating the Period of Utero-Gestation, etc. Aside from these features, its size and weight recommend it. It is claimed to be the smallest and lightest Visiting List, published. A very great advantage, when one considers the number of articles the physician has to carry in his pockets. THE MEDICAL AND SURGICAL REPORTER has decided not to publish a Visiting List this year, but has adopted and offers for sale this one to its subscribers.

---

# CURRENT LITERATURE REVIEWED.

IN CHARGE OF ELLISTON J. MORRIS, M. D.

---

THE UNIVERSITY MEDICAL MAGAZINE for January. Dr. James Tyson contributes a clinical lecture on

**Croupous Pneumonia.**

The author states that he has no doubt as to the propriety of bleeding in certain cases of pneumonia and the proper time to bleed is at the commencement of the disease. He thinks it is the frequent breathing next to the character of the pulse, or sometimes even the first, which should determine the taking of blood; and he would prefer even to run a little risk, if the pulse rather contra-indicated it, should the patient breathe as rapidly as in one of the cases described—72 times a minute. No symptom, as a rule is more promptly relieved by a bleeding in pneumonia than pain. He thinks fewer cases can be hurt by bleeding than we are led to suppose, that we bleed too little in this disease and if we bled more frequently more cases would get well.

Dr. M. Howard Fussell describes a case of

**Tetany.**

The case is remarkable in showing in the same individual a typical case of tetany and of epilepsy. The epileptic siezures were usually preceded by an attack of tetany, though the first and last convulsions occurred when the child was free from tetany. It would seem as if the two diseases, certainly in this patient, were simply variations of the same condition. Laryngismus stridulus was a prominent symptom in the attacks of tetany. The child *was not rachitic.* The tetany occurred in the spring and fall and disappeared in the summer and winter. The causation of an attack in this case appeared frequently to be disturbances of digestion. He concludes that tetany and laryngismus stridulus are identical conditions and not distinct diseases.

Dr. William Osler reports a case of "Parotitis in Pneumonia," which is interesting on account of the rarity of the complication. The patient died.

The same author also reports a "Case of Pericarditis Treated by Incision and Drainage." The points of interest about this case are: (1) A septic pericarditis following acute necrosis of the bones of the nose; (2) the peculiar delirium occasionally seen with pericardial effusion; (3) the onset, two weeks after operation, when the patient had been doing well, of excessive cardiac debility, probably due to myocarditis. The patient died. No autopsy was obtainable.

Dr. James Wallace contributes a scholarly paper on "Gonorrhœal Ophthalmia." Dr. Albert S. Ashmead in a short paper on "A Source of Infection on American Prairies" denies that typhoid fever can arise *de novo* and is inclined to attribute outbreaks of the disease among emigrants to infection of the streams by previous emigrant trains.

The remaining paper is by Dr. William Goodell on "The Great Medical Error of the Day." In it the author states that too much stress is laid upon lesions of the reproductive organs in the treatment of the diseases of women and too little heed is paid to the nervous system. The author cites cases to prove the position taken in the paper.

THE BRITISH JOURNAL OF DERMATOLOGY

for December. Sir Dyce Duckworth, M. D., describes

**A Case of Linear Atrophy of the Skin, with Hyperæsthesia of Adjacent Parts.**

Three months after an attack of typhoid fever the patient, a well-nourished lad of fifteen, noticed marks on his left thigh at the outer aspect, and similar ones above each ankle on the outer side of the lower legs. About the same time he experienced undue sensitiveness in the neighborhood of these marks, and also over adjacent parts, as on the outer aspect of the thigh. Examination showed several stripes of linear atrophy running across the outer part of the left thigh and on the outer side of both lower limbs above the malleolus. The knee-jerks were natural. The prognosis in any such case is good, but it is not to be expected that the integuments will ever again become natural. The therapeutical indications are to restore the general level of nutrition by good diet, and to employ such remedies as arsenic, iron, and cod liver oil. Warm sea-water baths, or peat baths, may be recommended, and feeble galvanic currents applied for short periods to relieve the hyperæsthesia. The appearance presented by the atrophic stripes is exactly that seen after prolonged distension of the integuments from obesity, lipomata, pregnancy, or chronic dropsy from cardiac or renal disease.

But in these cases the condition arises without any recognizable distension, and is probably due to neuritis involving both sensory fibres and those regulating the nutrition of the affected area.

Drs. G. G. Stopford Taylor and Frank H. Barendt report

**Three Cases of Adenoma Sebaceum in One Family.**

The author belives that the name Adenoma Sebaceum is well chosen; for it is a benign growth beginning in a gland, and the adjunct sebaceum marks its nature, both of which points the microscopical evidence completely confirms. The fact that some psychic disturbance is almost invariably present is of use in arriving at a diagnosis. The treatment is unsatisfactory, although surgical measures have improved the disfigurement in certain cases, especially where the papules are few in number. The author believe that the disease is of the nature of a congenital overgrowth of the sebaceous glands.

Dr. S. Pollitzer reports

**A Case of Xanthoma Tuberosum Multiplex.**

The noteworthy points in this case are a slight tendency to grouping in geometric figures (the parallel streaks on the left arm and the ring on the right palm) and the reddish hue apparent in some of the patches. This later fact appears to the author of especial importance in view of the relations between this form of Xanthoma and the disease as it occur in glycosuria. In a large number of cases of Xanthoma there is a distinct history of hepatic disturbance, especially of jaundice. In this case there was also probably some liver trouble, if we may interpret the attacks of severe epigastric pain referred to as due to biliary colic.

The same author also reports a "A Case of Xanthoma Diabeticorum"

Alfred G. Francis, M. B., reports "A Case of Lymphangioma Circumscriptum Cutis."

---

THE JOURNAL OF CUTANEOUS AND GENITO-URINARY DISEASES

for January. Dr. Albert S. Ashmead presents

**Extracts from a Japanese Work on Syphilis,**

published in Kioto in 1801. According to the author, syphilis existed and was included among skin diseases as far back as the Chu dynasty, that is about seven hundred years before Christ.

His own remedies are the following: Celestial pills which contain calomel; eliminating pills, which also contain calomel; silver nitrate pills, which contain mercury and nitrate of potash; five-element pills (having some relation to the sacred elements, wood, fire, metal, earth, water), which contain calomel; yellow illuminating powder, which contains calomel; precious-dew powder, which contains calomel; and another medicine which also contains calomel.

Poisoned diet—he means one a diet unfavorable to the patient—is advised as being unfavorable to the poison of syphilis. One poison drives out another; similia similibus. Calomel is not recommended at the beginning of syphilis.

Dr. H. Radcliffe-Crocker, of London, England, contributes a paper on "Lupus Erythematosus as an Imitator of Various Forms of Dermatitis," describing numerous cases in which the disease simulated other affections of the skin. The paper is illustrated by a beautiful chromo-lithograph of one of the cases in which the disease simulated was lichen planus.

The remaining papers in this issue are: "A Case of Mycosis Fungoides" by Dr. R. A. McDonald McDonnell; and "Clinical Notes on Skin Diseases" by Dr. W. F. Breakey.

---

THE INTERNATIONAL JOURNAL OF SURGERY

for December. Dr. F. Byron Robinson contributes a paper on

**The Pathology of the Fallopian Tube**

in which he comes to the following conclusions:

1. The pathology of the Fallopian tube should be studied in regard to its structure, function and its connection with the peritoneum.

2. The inflammatory processes may be divided into three varieties, viz.: 1, endosalpingitis; 2, muscular salpingitis; 3, perisalpingitis (pelvic peritonitis).

3. The inflammatory process in the peritoneum spreads from the abdominal end of the tube in nearly all cases.

4. The nodular masses found in the pelvis are perisalpingitis and not cellulitis.

5. Autopsies demonstrate that severe perisalpingitis or pelvic peritonitis may exist, but the subperitoneal tissue will be as white as snow, as beautiful as hoar-frost.

6. Convoluted, contorted or spirally twisted tubes are accompanied by tubal colic. Such tubes are congenital or the result of subinvolution. The *tenia* tubæ enhances the condition.

7. At the bottom of most tubal trouble can be traced labor, abortion, gonorrhœa and sepsis.

8. A pyosalpinx can be changed into a hydrosalpinx and recover without operation.

9. Primary sarcoma, cancer, or tuberculosis of the tubes are quite rare.

10. No tube should be removed unless pathological conditions can be demonstrated in it, except for myoma and hysterical convulsions.

11. A prosalpinx should be removed on discovery.

12. Adhesions alone may be a sufficient cause for tubal removal on account of nerve pressure and irritation.

13. A large portion of the evil influences of tubal diseases is due to the irritation being transmitted to the abdominal brain, and then emitted to every viscus, destroying their rhythm and nutrition.

14. In removing tubes the ligature should be placed close up to the uterus, so that the menstruation will stop immediately by removing all the "automatic menstrual ganglia" belonging to the tube.

15. Uterine curetting in tubal disease should be judiciously employed. The author knows of several deaths from such procedure.

16. There is no doubt that much tubal pathology results from tinkering with the uterus, the introduction of sounds, unclean instruments, electrodes, and unnecessary curetting. Dilatation of the uterus is sometimes followed by tubal pathology.

Dr. Thomas H. Manley describes

**A Bloodless Operation for Hemorrhoids.**

The author advises local anæsthesia by means of cocaine applied hypodermically as by its means the patient is much more manageable than when under ether. The next step is thorough dilatation without which the operation will be a failure. To be painless and safe the dilatation must be gradual and steady or the muscle will be ruptured and the patient left incontinent. The third step in simple hemorrhoids is the separate treatment of each tumor by forcible pressure-massage. Before this is commenced, the entire cluster should be wiped clean and dry and then be freely mopped with the cocaine solution. Now, each hemorrhoid is separately seized, close to its base, firmly, between the tip of the thumb, index and middle fingers; first, put on a moderate, but full stretch; then twisted, and finally, so completely crushed that is reduced to a pulp, and none of the investing tunics remain, except the mucous membrane and its under stratum of fibrous tissue. When this has been completed, the entire mass is again pressed up, inside the sphincter; a suppository of opium introduced, a pad and bandage applied, when the patient is returned to bed. An active, but painless inflammation follows; and, as a rule, within two or three weeks, resorption and atrophy have so reduced the vascular masses that nothing now remains but their shrunken, diminutive stems.

Dr. Samuel E. Milliken discusses

**Diseases of the Joints in Children.**

The author cautions against the acceptance of the well known phrase "growing pains" as applied to children. Pain is no more physiological in the child than in the adult and when it occurs should be investigated by the physician. He also advises the use of an anæsthetic in any tedious examination of a joint. Its use is advisable not alone to determine the lesion more readily but also because the subsequent treatment of the child can be carried out with less resistance if pain is not caused at the first examination. Conservatism should be the motto in the treatment of joint disease in children. It is the author's opinion that excision is only advisable in extreme cases as partial arthrectomy usually meets the requirements of such emergencies.

Dr. L. J. Lusk reports a case of

**Penetrating Wound of Anterior Fossa through Orbital plate of Frontal Bone—Recovery.**

The patient had been thrown by a runaway horse against a lamp-post, driving a piece of gas-pipe, with a blunt end five-eighth inches in diameter, into the forehead a depth three of and one half inches. Her swaying body remained suspended in this position until removed by two strong men; one lifting the body, while the other pressed her head off the tube. The bones uniting to form the orbital floor were as completely removed as if it had been the work of the most skillful hand. There was also a fracture of the nasal eminence of the frontal bone. The eye-ball was uninjured except being completely separated from its attachments. Hemorrhage was quite profuse, but was controlled by cold compresses of sublimated water. An early hypodermic injection of ¼ gr. sulphate of morphine was given. The parts were thoroughly washed with hot sublimated water, 1-2000. At the point of deepest penetration, which was about three and one-half inches, the author used a 1-3000 solution in the cavity, the patient lying on her back; by turning slightly the face downward, the water ran out. After making the parts as thoroughly aseptic as possible, several strands of aseptic silk were introduced in the deepest perforation and the flaps united by interrupted sutures. The external dressing consisted of iodoform and boracic acid, and the whole covered with sublimated gauze and absorbent cotton.

Dr. A. B. Judson contributes a paper on "The Importance of Early Attention to the Disability Caused by Infantile Paralysis." In the department of the journal devoted to Railway Surgery, Dr. Emory Lanphear discusses "Meningeal Hemorrhages and their Treatment;" and Dr. George Chaffee contributes a paper on "Railway Surgery,

Railway surgeons and their Societies." This issue also includes a report of the Annual Meeting of the New York Association of Railway Surgeons.

## NEWS AND MISCELLANY.

### Eleventh International Medical Congress.

A letter directed to the undersigned by the Secretary-General of the Eleventh International Medical Congress and dated December 19th, 1893, contains the following communications:

"American members will pay on the English, French, and Italian railways single fares for double journeys, and will obtain a reduction of twenty per cent. on fares for Italian round-trip tickets.

"The documents required for their identification will be sent to you in January, and Americans intending to visit the Congress will have to apply to you for them.

"Full particulars concerning the journeys will accompany the documents.

"Messers. Thos. Cook and Son, London, Paris, Rome, and Naples, should be applied to for accommodation and for tickets for the excursions at Rome, Naples, and to Sicily. Such excursions will be arranged at Rome under the guidance of Mr. Forbes, member of several scientific societies and correspondent of the "Times"—for Naples, three days, including Vesuvius, Pompey, Capri, Sorrento, Castellamare, Bajae, etc.—for Sicily, ten days from Naples, including Messina, Taormina, Catania, Girgenti, Siracusa, Palermo, and return to Naples.

"The fares for members of the Congress will be considerably reduced and comprise hotel accommodations, carriages, guides, boats, etc.—about 70 frcs. each, for the three days, and 285 frcs. for the ten days.

"Full particulars concerning these excursions will be contained in a leaflet to be added to the instructions and documents for the journey."

From former communications the following are herewith quoted. The members' fee is five dollars, that of their wives or adult relations two dollars each. Checks or money orders may be sent to Prof. L. Pagliani. Rome, Italy. Credentials have been promised in the near future. When they arrive (none were received last year), they may be too late for many who have started or are about to start. The undersigned, who is not informed of the cause of delay, proposes to supply in as official a form as he thinks he is justified in doing, credentials which are expected to be of some practical value. The North German Lloyd has promised to recognize them. It is suggested, besides, that a passport may increase the traveler's facilities.

Only the North German Lloyd (22 Bowling Green) and the Compagnie Generale Transatlantique (3 Bowling Green) have thought fit to grant any reductions to Congressists.

The reduction on Italian railways are available from March 1st to April 30th.

A. JACOBI, M. D.,
110 W. 34th Street, New York.
January 11th, 1894.

### Excursions to the National Capitol.

The Royal Blue Line has arranged a series of personally conducted three day tours from New York, Newark, Elizabeth, Trenton and Philadelphia to Washington, under the supervision of Thos. Cook & Son, the famous Tourist Agents. The dates selected are January 25, February 15, March 8, 29, April 19, 26, and May 10 and 17. The rate from New York, Newark and Elizabeth will be $13.00, from Trenton $12.25, and from Philadelphia $11.00, which will include transfers between depot and hotel and first-class hotel accommodations at Washington. The train will leave New York on above dates from station, foot of Liberty Street, 9.00 A. M., leave Newark, C. R. R. of N. J., 8.55 A. M., Elizabeth, Royal Blue Line, 9.31 A. M., Trenton, P. & R., 10.20 A. M., Philadelphia, 12th & Market Streets, 11.26 A. M., and 24th & Chestnut Streets, 11.42 A.M., and will arrive at Washington 3.00 P. M.

The tickets will be valid for the return journey on any Royal Blue Line train within three days, including first day of sale, thus affording tourists an opportunity to visit the public buildings and places of interest in and about the Capitol.

For more detailed information call on or write Thomas Cook & Son, 261, 1225 Broadway, New York, or 828 Chestnut Street, Philadelphia.

## ORIGINAL ARTICLES.

### THE PHYSICIAN.*

H. D. HOCKENBERRY, M. D, West Sunbury, Pa.

As has been the custom, it becomes my duty, as retiring President of this society, to deliver before you the "Annual Address." And in attempting this it is certainly with a good deal of trepidation, knowing my unfitness for such an undertaking. The duties of the medical profession are not such as tend to develop the powers of rhetoric and oratory.

The physician is a man of deeds rather than of words; more accustomed to silent cogitations by the sick bed or in his office, as he notes the symptoms in the case before him and attempts to explain their cause, or as he decides upon the treatment best calculated to promote the recovery of the sufferer. He lacks the experience that comes to men in other professions, who take part in public discussions, or whose duties place them behind the pulpit, or upon the rostrum of the lecture room.

But if the physician is not a "good speaker," he is a "good hearer." The very training received in the investigation of disease, in the careful and minute observations and accurate interpretation of symptoms, educates his senses, and develops his powers of observation, making of him an attentive and critical listener, and hence, my greater timidity in coming before you.

But not to weary you with my apologies, allow me to say, by way of introduction, that the meetings of this Society are a "means of grace" that none of us can well afford to lose. We need the friendly associations of our fellow physicians. We need the mutual interchange of experience and opinions. None so learned but that he may be profited by these; none with so meagre an experience but that he may furnish a suggestion of value to others. Without these, we are liable to become narrow minded practitioners, to fall into ruts, to lose interest in our work, and its duties become the "tread mill" of our existence.

But more than this, our society relations tend to destroy the spirit of envy and jealousy that is so liable to arise among men engaged in the same calling. Instead, there prevails a spirit of peace and good will. We recognize the fact that we are a brotherhood whose end is to relieve suffering humanity; to make man physically stronger, and as a consequence, morally and intellectually better, because man's moral and intellectual attributes depend upon the development of his physical organization. Having therefore the common purpose, by our united efforts we are able to accomplish the greater good.

Another year of society work is done, and we have reason for congratulations that not one of our number has dropped out of practice by reason of death or failing health. We yet present an unbroken front, able and willing and anxious to do battle against disease. As we are about to enter upon a new year with its attendant

*Annual Address before the Butler County Medical Society by retiring President.

duties and responsibilities, would it not be well to take a retrospect of the past year?

Recall its failures and successes; take an inventory of our medical experience, that we may know whether or not we have been profitable servants to the well being of society? And as we come to render an account of our stewardship, is it with the pleasing satisfaction of knowing our faith pleases, in that our talent has gained other talents? Or do we come with fear and trembling, bringing the talent entrusted to us carefully preserved in a napkin, having failed to invest it with profit? We are under obligations to society, not only to protect and preserve the medical truths entrusted to us, but as we enjoy the records of the accumulated experience of generations of the past, so we owe to the generations of the future such a use of our advantages of experience as will add to the records of medical knowledge; else we deserve to be condemned as unfaithful and unprofitable servants.

We look back over the past, not with vain and foolish longings for its past advantages and pleasures, but because the past offers the only land marks by which our future is to be directed. Nathaniel Hawthorne makes a character in one of his stories to say, "Whatever we seek to do of our own free motion, a dead man's icy hand obstructs us." It is not true. This "icy hand" of the dead past is leading us into wisdom's ways. It is the finger-board that points us towards the haven of truth.

I might also have added, in the same connection he says, "We die of the same remedies with which dead doctors killed their patients."

We know nothing except as it is revealed to us by past experience. Scientific knowledge is founded upon this. We have been sneeringly called "empirics." Yet this epithet intended as a term of reproach, is most highly complimentary, as "empiricism" is a foundation of rock upon which is built the superstructure of science, and upon this the winds and rains of criticism and opposition have no effect.

"If," says Dr. Sam'l Johnson, "no use be made of the labors of past ages, the world must remain always in the infancy of its knowledge."

Experience is the wood and stone, the brick and mortar, the iron, the brass, the silver, the gold and the precious gems which the builder uses in the construction and decoration of the magnificent temple of "Eternal and Infinite Truth." We may not be the architect who plans and supervises the building. It may not be ours to fill the places of cunning and skilled workmen. We may be but humble hewers of wood or bearers of stone; but whatever part we take in this great work let it be done honestly, carefully, thoroughly, so that the storms of time will not overthrow it. And to this temple all future generations shall come to worship, because within its holy place dwelleth the Divinity of Truth.

But not only is it proper and profitable to review the past that we may glean knowledge from the fields of experience that have been harvested, but also that we may have a true appreciation of the profession to which we belong.

"Value yourself at what you are worth," was the saying of one whom I looked on as possessing great practical shrewdness. Value the profession at its true worth is a very praise-worthy egotism. As the veteran soldiers gather around their camp-fires and recount the deeds of military skill and courage of the past, and are thereby stimulated to daring acts of valor in the 'morrow's fight, so may we, by recalling the efforts of those heroes of the medical profession who in face of all opposition and discouragements have made valuable discoveries in medical science, be stimulated to renewed efforts in our warfare against disease, that new remedies and new methods of treatment be discovered, and the sufferings of mankind alleviated.

It is with excusable pride I point to the successes of the medical profession in the past, and comparing those with what has been done by other professions and in other callings, am ready to make this assertion without fear of contradiction. That the medical profession in the importance of its work, in what it has done to overthrow ignorance and superstition, and in the unselfishness of its charity, stands second to no other calling or profession. And I say this, with all respect to the honest and faithful efforts of others, knowing that we are all members of one body of which the eye cannot say to the hand I have no need of thee.

First, as to the importance of the medical profession. That we fully comprehend this, it may be necessary to consider what is the great purpose of our lives. What is the object of all labor in the various industries of the world? Why, the struggle to gain knowledge, wealth and honor? Are these the end of our existence?

It is possible to so lose sight of the chief end of life as to make of these the end, which are but means to an end. We acquire knowledge and wealth that we may live For this torrid heat and arctic cold are endured; the ocean's storms braved. For this rivers have been bridged, mountains tunneled, forests cleared, the wilderness made to blossom as the rose, and the barren desert to bring forth abundantly. All this that man may live. Let us emphasize this truth: *The great object of life is to live.* We are born with inherent desires for life. We are constantly struggling to overcome unfavorable surroundings, to understand the laws of nature, that by bringing ourselves into harmony with these, we may live. If then, the end of life is to live, that calling that has to do with man's physical organization must be of chief importance. The physician with scalpel and microscope studies the structure of the various organs of the body. By carefully conducted experiments he learns the functions of these parts. With like care he examines the structure of diseased organs, and notes their altered functions. He searches the animal, the vegetable and the mineral kingdoms for means to restore the diseased organs to a condition of health and normal function. But not only does he cure disease but, as a guardian of the public health, he instructs the people in those laws that govern their physical being, the observance of which promotes health and lengthens life. He selects the food best suited to further the growth and development of the body; he arranges the style and fabric of clothing; houses are built according to his plans. At his direction swamps are drained, waters are purified, sewers are laid, streets are swept, pools of contagion disinfected, and loathsome plagues eradicated. The surgeon's knife is no longer a thing of terror, and under the influence of anæsthesia, the offending member is removed and many valuable lives are saved. But why the further enumeration of these valuable services when the importance of the profession of medicine is so evident.

But again, no class of men have done more to overthrow ignorance and superstition, and among none others, do we find permitted the same freedom of investigation and discussion. We are not fettered by "ancient theories" or "old time dogmas," to which we must give unlimited credence. And rejecting these does not subject us to excommunication from the profession. We value the truth not because it is old, neither because of its general acceptance, nor yet because it has associated with it some marvelous story of supernatural revelation, but because it is truth and has stood the test of rational investigation.

We are perfectly free to reject a theory, notwithstanding its age and general acceptance, if it has been weighed in the balance of scientific medicine and found wanting. And for such rejection, we are in no danger of being brought before a tribunal of inquisition and condemned to professional death. Well for a sister profession did the same freedom of search after truth prevail. Witness the trial and condemnation of Briggs, who was crucified by his brethen, between Bob Ingersol on one side and Tom Paine's ghost on the other.

The medical profession has never been found stoning Stephen, burning witches, or hanging Quakers. Accused by the priest hood before Pilate, or doing God's service in hunting to the death those who dare to preach doctrines contrary to the accepted religion, is the history of all persecution.

And "Great is Diana of the Ephesians" has been the battle cry of superstition in all ages, as its votaries have waged their cruel and unrelenting war against science. As you all know the medical profession originated in the separation of medical truths from their union with the superstitions of priest craft. Primitive man, with no experimental knowledge upon which to base a theory of disease, looked upon the pain and sickness as indicating the wrath of the Deity supposed to have created man and having unlimited powers over the work of his creation.

To understand, and to be able to appease the wrath of this offended Deity, were attributes assumed by certain ones who, by working upon the credulity of

their fellows impressed these with a belief in such pretended supernatural powers. In this way was originated the priesthood or profession of theology. That the priests might retain their hold upon mankind, it was necessary, that in their treatment of the sick, these efforts should be attended with some degree of success, and this led to the study of the phenomena of disease, and means to cure this. Thus the first medical truths were associated with priest-craft and the priests were the first physicians.

But the practice of medicine by these priest-physicians was so mixed up with the rites and ceremonies, the offerings and incantations of their religion that the truth was hidden from the public gaze, and the cures effected were supposed to have been the result of supernatural agencies. About the year 450 B. C., when the learning of Grecian philosophy was at its height, Hippocrates effected the separation of which I have spoken, and medicine divorced from priest-craft has ever since maintained a separate existence, its followers recognizing Hippocrates as the "Father of Medicine." But even though more than twenty-three centuries have passed since then, and notwithstanding the great advancement of medical science, the ancient teachings of the priesthood have retained such hold upon the minds of men, that it is no uncommon thing to hear sickness spoken of as the mysterious ways of an inscrutable and all-wise Providence, and, also, to hear the Deity importuned to allay sickness; and in the minds of many, the visits of the clergy are as necessary to the well-being of the patient, as are the visits of the physician. Superstition has a mighty hold upon the world, and with its twin-sister, ignorance, obstructs the path of progress, and shuts out the light of scientific truth.

But not only is the medical profession of first importance to the well-being of society, and a champion and an advocate of the truth, but its followers are living examples of the principles taught by the "Peasant of Nazareth," who gave to the world the commandment of Love. "I was an hungered and ye fed me, naked and ye clothed me; I was sick, and ye visited me." Where is the class of men so faithful in the performance of their duties as physicians. The profession of medicine having for its end the common good of mankind, knows nothing of national enmity, political strife or sectarian dissensions.

It dispenses its benefits without stint to men of every country, party or religion.

The physician is the good Samaritan, who binds up the wounds of the man fallen among thieves, although a priest and a Levite had passed by without being touched by the sufferings of the unfortunate man. No other class of men dare as much, risk as much for the welfare of others. Men excited by the noise of battle and stimulated by the presence of hosts of comrades, have risked their lives in the performance of most wonderful deeds of valor. The physician with no thoughts of worldly applause, with no thought of the small pittance he may receive for his services, in the slums of vice and in the midst of the filth and wretchedness of poverty, exposes himself to the deadly contagion that the poor sufferer be relieved, or that the deadly epidemic be stayed. Such an one is a thousand times more a hero than he who faces the destructive fire of cannon and musketry. Men who have passed through the horrors of war without a thought of cowardice, stand with quaking hearts and blanched faces in the presence of contagious diseases, or flee for their lives from the plague-smitten district. While the physician goes about his work of caring for the sick with a cool head and a sympathetic heart, administering medicine to relieve their sufferings and cheering words of encouragement to relieve their despondency. A veritable angel of mercy to the poor sufferers. Not only to cure disease, but to prevent it as well. No labor is too hard, no risk is too great that the cause of disease be discovered and its ravages prevented. None are so poorly paid as the physician. Much of his work lies among the poor and vicious, who are sick because of their poverty and wickedness. To these he gives his time, and very often medicines. All of which are usually received in a sort of you-are-obliged-to-do-it spirit, and little thanks for his kindness.

Even in the minds of the general public, there prevails the notion, that the physician is under greater obligations to give his services without compensation, than are men in other callings.

The miller may refuse the flour, the butcher the meat, the merchant the clothing, that the poor family be fed and clothed. But let the physician refuse to visit this same family, such a hub-bub of righteous indignation is stirred up against him as no one would have the courage to face. The reason of this is the fact that such charity is very rarely withheld. The priest may refuse his blessing to the dying sinner. But none so vile that he may not receive the kindly offices of the physician who alleviates his pain without condemning his vice.

But what of all this. If these things are true, does not such an egotistic view of the profession of medicine and its value tend to fill us with an exalted sense of our importance? That in the haughtiness of spirit we cry out, is not this great Babylon that we have built? Not so. To realize all this, to value the profession at its true worth, impresses us with the greater responsibilities resting upon us by reason of the high character of our calling, whereby we have the greater opportunities for doing good. And we dare not neglect the voice of duty that comes mingled with the groans of sick and dying.

From the position we occupy, we are able to see the great things that have been done in medicine. But in the line of our vision is also to be seen very much remaining yet to be done. Epidemics sweep over our land, in whose wake are to be heard the lamentations of the mourners who sorrow for the loss of those fallen under the blightings of the deadly plague. Men and women are dying with diseases so loathsome in character as to make of them objects of dread and disgust to all around, while their bodies are racked with most excruciating pains. The physician stands by, powerless to stay the progress of the disease or to relieve the suffering it occasions.

In our cemeteries, as we read the inscriptions upon the stones that mark where the dead are laid, we find that but very few have reached the limit of man's existence. In infancy, in childhood, and in early manhood, the greater number have passed away. And this, not because a kind Providence has seen fit to remove them from the temptations and snares of a wicked world, but because the laws of hygiene have not been perfectly understood, because the nature of contagious diseases has not been discovered, and because we have not been able to eradicate the influence of heredity. Are there not great opportunities of usefulness for us in the fields of medicine, not only the more skillful application of those truths already known, but the discovery of new truths? Before us lies the ocean of investigation, upon which we may launch our barks upon a voyage of discovery. Already there are signs of our nearness to land. There comes floating towards us strange forms of microscopic life. We have picked up the "carved wood" of cell propagation and soon we may expect to take possession of this new world of unknown truths, upon whose shores we will plant the banner and cross of Medical Science.

---

**Chloralamid a Remedy for Sea-Sickness.**

Mal de mer is an ailment, to the treatment of which I directed attention at the recent meeting of the Medical-Climatological Section of your Exposition. I there stated that evidence very complete and very convincing, existed as to the utility of a solution of chloralamid and bromide of potassium, known as chlorobrom, in arresting the retching and in allaying the mental depression which accrues after the stage of active vomiting had passed. Since then evidence has been published in the *Lancet* by ship surgeons which notably proved its prophylactic action, if certain medicinal and dietetic requirements be carried out, previous to the passenger going on board ship. These requirements are simple, and need not now be mentioned. The solution is potent, palatable and safe. It is always retained, and I have no hesitation in saying that, at last, we have found a remedy for "The swooning sickness of the dismal sea."—*No. Amer. Practitioner.*

---

LONESOME.—The feeling of superiority in the sterner sex is inborn.

"Mamma, do you think you'll go to heaven?" said Jack, thoughtfully looking into his mother's face.

"Yes, dear, if I'm good," said the little mother, cautiously, wondering what would come next.

"Then please be good, for papa and I would be lonesome without you."—*Kate Field's Washington.*

# COMMUNICATIONS.

## THE HYPODERMIC INJECTION OF SULPHATE OF MAGNESIUM AS A PURGATIVE.*

J. PERCY WADE, M. D.,†

In 1873, M. Luton, made the statement, that ten centigrammes of Sulphate of Magnesium injected under the skin, regularly produced purgation. Claude Bernard had previously stated that when injected into the vein Epsom Salts produced a purgative effect.

These statements appear to attract but very little attention on the part of clinicians and slight notice is given to them in works on Therapeutics. However, Dr. Horatio C. Wood (Therapeutics; 8th edition, 1891; page 722) makes a slight reference to the former, although considering the practice a very doubtful one.

Dr. Matthew Hay, who has contributed so much to our knowledge of the physiological action of the saline purgatives, asserts that the Sulphates of Magnesium and Sodium do not purge when injected into the blood, or subcutaneously. In the latter case, he makes an exception in cases where in virtue of the injection a local irritation of the abdominal subcutaneous tissue is produced, "which acts reflexly on the intestines, dilating their blood vessels, and perhaps stimulating their muscular movement." Dr. Hay also states that when injected into the blood, Sulphate of Magnesium is powerfully toxic to the system, "paralyzing first the respiration and afterwards the heart and abolishing sensation, or paralyzing the sensory motor reflex centres."

The dose that M. Luton used, and found to act as an effective purgative was ten centigrammes, equivalent to 1.54 grains. Acting upon a suggestion of Dr. Rohé, the superintendent, to subject the question to a further clinical observation, forty-six patients were selected, who suffered from habitual constipation and required from 2 ozs. to 3 ozs., of a saturated solution of Magnesium Sulphate to produce one or more free movements of the bowels.

A two-per-cent. solution of Epsom salts in sterilized water was used. The hypodermic syringe employed had a capacity of two drachms, and when not in use, was kept in carbolized oil. Just previous to use, the needle was sterilized by steam. The dose varied from 1.86 grains to 4.5 grains. The smallest dose was first tried, and at each subsequent injection was increased one-half grain, in order to determine whether a slight increase in the dose would cause a free evacuation. It was found that the small dose acted as efficiently as the slightly larger.

In only one case was the largest dose (4.5 grs.) employed. This was a woman in whom 2 ozs. of a saturated solution of Magnesium Sulphate had previously failed to produce a movement. The subcutaneous injection caused a free evacuation in seven hours.

The site of the injection was the left arm, at the outer aspect midway between the elbow and the shoulder. In none of the cases was there any local reaction at the point of injection. A small swelling or slight tenderness was produced by the distension of the connective tissue which disappeared in a few hours. No induration or abscesses occurred, and the slight discoloration of the skin passed off in a day or two.

The injection was made 100 times in the 46 patients, and was successful 67 times or 67 per cent. and failed to act 33 times or in 33 per cent.

In 53 injections it produced one evacuation of the bowels; in ten, it produced two movements, and in four it produced three evacuations.

In only two patients were the injections a constant failure and both of the patients were of the class of melancholia with habitual constipation, who resisted nearly all purgatives.

In nine cases, the injection of 1.15 grs.—one-half the average dose—was repeated in one hour and caused two evacuations in five cases; in one, three movements; in two, one; in one, failed to act at all. This action shows that a small dose repeated in a short time has a better effect than one single dose of larger size.

In ten selected cases a comparison wa made between the hypodermic injection

* From advance sheets 96th Annual Report of Med. Hosp., for the Insane.

† Assistant Physician, Maryland Hospital for the Insane.

2. Trousseau and Pidoux, Therapeutics, Vol. 2, Page 165 Wm. Wood & Co. 1880.

of Magnesium Sulphate and the exhibition of a saturated solution by the mouth. In seven cases, or 70 per cent., the injection produced free evacuation; whereas one oz. given by the mouth acted in only three or 30 per cent.

The shortest time for the injection to produce an evacuation was three hours; the longest fourteen hours—the average being seven hours.

As to the consistency of the stools—45 may be said to have been watery, resembling those produced by a free saline purgative; in 11 they were mucilaginous in character, and the remaining 11 were the ordinary stools.

No action was noticed upon the general system following the injection.

In 50 injections noticed ½ hour after the injection, no rise in temperature, pulse or respiration occurred.

The indications for the use of the drug by hypodermic injection are obvious. In cases of gastric inflammation, where a purgative is required and the stomach rebels; in abdominal surgery, where a purgative by the mouth is apt to cause vomiting and in cases where the patient is unconscious, and unable to swallow, as in apoplexy, the hypodermic use of this purgative would be valuable.

In none of the 46 cases did such indications arise, but the work was done as an experiment and to demonstrate the value of the drug as a therapeutic agent when given subcutaneously. No explanation is offered as to its physiological action. That it does act when so given is a fact.

The effect could not be attributed to suggestion, as the patients did not know with what object the injections were made; besides, insane patients are notoriously difficult to influence by suggestion.

As stated before, the injections were always made into the arm, so that the aid of reflex irritation, in the sense of Matthew Hay, cannot be invoked in explanation.

## THE RELATION OF PELVIC DISEASE AND PHYSICAL DISTURBANCES IN WOMEN. SOME FURTHER OBSERVATIONS AND RESULTS.*

GEORGE H. ROHÉ, M. D.,† CATONSVILLE, MD.

In my report for 1892, I gave the detailed history of eighteen cases of insanity in women, in whom the uterine appendages were removed for ovarian, tubal or other pelvic diseases. Since that report four additional cases were operated upon. The following table gives a summary of the cases, together with the results in each case, to December 1, 1893:

A review of the cases will show that even in apparently the most hopeless cases, a beneficial effect upon the mental functions is obtained by the removal of a persistant source of local irritation. Thus in one case of hystero-epilepsy with violent maniacal attacks, lasting over eight years, complete recovery was obtained.

In four cases of puerperal insanity, two of over five years standing, three recoveries followed the operation, and the remaining case was greatly improved.

Three cases of profound melancholia recovered sufficiently to be discharged from the hospital.

In nearly every case operated on decided physical and mental improvement were noted.

While no claim is made that gynecological operations are generally indicated in insane women, it is held that where sufficient disease exists to demand treatment on its own account, the mental disturbance of the patient should be an additional reason for early and effective interference.

In the present conservative tendency among gynecologists, there is danger of delaying radical measures too long. If this delay is injudicious in the sane, as I firmly believe it to be, it is no less in the insane where recovery of mental health may be retarded or rendered impossible, by hesitancy or neglect.

I have been subjected to criticism, some of a rather savage character, for my work in this line. Some of my critics know, confessedly, little of the great advances made by modern gynecology, while others were no less ignorant of the results of recent studies of mental pathology. I have refrained from replying to these criticisms because I could afford to await results. The facts here presented will, I am sure, be regarded by all unprejudiced minds as sufficient answer to the criticisms upon my course.

## Record of Operations upon Women with Pelvic Disease, in the

| No. of Case. | Date of Admission. | Duration of Insanity at time of Admission. | Age. | Social Condition. | Form of Insanity. | Local Disease. |
|---|---|---|---|---|---|---|
| 1 | Dec. 19, 1886. | Second attack. Ten weeks. | 33 | Married. | Puerperal mania. | Lacerated cervix. Ruptured perineum. Adherent ovaries. |
| 2 | May 21, 1890. | Four months. | 32 | Married. | Melancholia. | Lacerated cervix. |
| 3 | Feb. 26, 1890. | Three months. | 39 | Single. | Hysterical mania. | Anteflexio uteri, firm adhesion of right ovary and tube. |
| 4 | Mar. 2, 1891. | Three months. | 31 | Single. | Melancholia. | Enlarged ovaries. |
| 5 | Oct. 5, 1891. | One week. | 30 | Married. | Melancholia. | Cystic and adherent ovaries. |
| 6 | Oct. 12, 1891. | One year. | 29 | Single. | Simple mania. | Retroversio uteri, adherent ovaries. |
| 7 | May 16, 1890. | Second attack. Three days. | 37 | Married. | Puerperal mania. | Lacerated cervix, adherent ovaries. |
| 8 | Mar. 30, 1885. | Unknown. | 23 | Married. | Hystero-Epilepsy with mania. | Cystic ovaries. |
| 9 | Aug. 23, 1887. | Four months. | 39 | Married. | Puerperal mania. | Lacerated cervix, adherent ovaries. |
| 10 | Apr. 4, 1890. | Epilepsy. Ten years. | 25 | Single. | Epileptic insanity. | Ligamentary cyst size of an orange. |
| 11 | Oct 22, 1888. | Three months. | 24 | Single. | Melancholia. | Cystic ovaries, and congested and tortuous tubes. |
| 12 | July 11, 1891. | Epilepsy. Seven years. | 23 | Single. | Epileptic insanity. | Double pyosalpinx and ovarian abscesses. |
| 13 | Dec. 28, 1891. | Third attack. Three days. | 28 | Married. | Puerperal mania. | Ruptured perineum. Enlarged and prolapsed ovaries. |
| 14 | Feb. 22, 1892. | Ten months. | 43 | Single. | Melancholia. | Cirrhotic ovaries. |
| 15 | Apr. 12, 1892. | Epilepsy. Nine years. | 24 | Single. | Epileptic insanity. | Cystic ovaries. |
| 16 | Oct. 31, 1882. | Two years. | 30 | Single. | Periodic mania. | Cystic ovaries. |
| 17 | May 14, 1892. | Two years. | 29 | Widow. | Paranoia. | Cystic ovaries. Trachelorrhaphy had been done for lacerated cervix. |
| 18 | June 7, 1892. | Five years. | 30 | Married. | Periodic mania. | Lacerated cervix, retroflexio uteri, cystic ovaries. |
| 19 | Sept. 12, 1892. | Two years | 30 | Single. | Hysterical mania. | Retroverted and adherent uterus, cystic ovaries. |
| 20 | Nov. 3, 1892. | Two years. | 23 | Married. | Melancholia. | Retroversio uteri, lacerated cervix, cystic ovaries. |
| 21 | June 11, 1891. | One year. | 17 | Single. | Periodic mania. | Enlarged ovaries and tortuous tubes. |
| 22 | May 26, 1893. | Five years. | 40 | Married. | Hystero-Epilepsy with mania. | Firmly adherent ovary on right side. Ovary and tube of left side absent. Ventral hernia from a previous abdominal section. |

## Maryland Hospital for the Insane, with Results to Dec 1, 1893.

| Date of Operation. | Operation. | Immediate Result. | Ultimate Result and Remarks. |
|---|---|---|---|
| Oct. 6, 1891. | Removal of uterine appendages; restoration of perineum; trachelorrhaphy. | Recovery. | Decided mental and physical improvement. Recently phthisis developed, under which she is rapidly losing ground. |
| Oct. 13, 1891. | Removal of the uterine appendages. | Recovery. | Physical improvement. No mental change. |
| Oct. 21, 1891. | Removal of the uterine appendages. | Recovery. | Decided physical improvement. No noticeable mental change. |
| Nov. 4, 1891. | Removal of the uterine appendages. | Recovery. | Decided physical and mental improvement. Patient at nine months nearly well. |
| Nov. 4, 1891. | Removal of the uterine appendages. | Recovery. | Physical and mental improvement. Patient discharged from Hospital October 1, 1893. Four weeks later she was run over by a railroad train. This may have been a case of suicide, but there is no evidence of this. |
| Nov. 10, 1891. | Removal of the uterine appendages. | Recovery. | Physical improvement. Slight mental improvement. |
| Nov. 25, 1891. | Removal of the uterine appendages. | Recovery. | Physical improvement. Mental recovery. Discharged recovered August 21, 1892. Remains well December 1, 1893. |
| Dec. 10, 1891. | Removal of the uterine appendages. | Recovery. | Discharged entirely recovered May 12, 1892. June 30, 1893, she had two hysterical attacks, following accidental death of a relative. She was kept under observation three weeks without any return of the attack. December 1, 1893, she remains entirely well. |
| Dec 15, 1891. | Removal of the uterine appendages. | Recovery. | Great physical and mental improvement. Patient from being one of the worst and most troublesome cases in the Hospital improved so much that she could be discharged from the Hospital November 28, 1893. |
| Dec. 30, 1891. | Removal of ligamentary cyst and uterine appendages. | Death. | Died in status epilepticus. Probably septicæmia. |
| Jan. 19, 1892. | Removal of the uterine appendages. | Recovery. | No mental change. |
| Feb. 9, 1892. | Removal of the uterine appendages. | Death. | Died of Septicæmia. |
| Mar. 9, 1892. | Removal of the uterine appendages. | Recovery. | Discharged entirely recovered May 8, 1892. December 1, 1893. remains well. |
| Apr. 20, 1892. | Removal of the uterine appendages. | Recovery. | Decided physical and mental improvement. |
| May 12, 1892. | Removal of the uterine appendages. | Recovery. | Convulsions less frequent but still persist. Slight mental improvement. |
| July 14, 1892. | Removal of the uterine appendages. | Recovery. | Very decided mental improvement. |
| Aug. 30, 1892. | Removal of the uterine appendages. | Recovery. | Improved considerably, but was removed from Hospital, and is now reported worse. |
| Sept. 12, 1892. | Removal of the uterine appendages. | Recovery. | Decided mental improvement, which continues. |
| Dec. 1, 1892. | Removal of the uterine appendages. | Recovery. | No mental change. |
| Jan. 19, 1893. | Removal of the uterine appendages. | Recovery. | Complete physical and mental recovery. Discharged April 1, 1893 Remains well, December 1, 1893. |
| Feb. 2, 1893. | Removal of the uterine appendages. | Recovery. | Decided progressive mental improvement. |
| Oct. 26, 1892. | Removal of ovary and tube on right side. | Recovery. | Operation too recent to give ultimate result. |

# REPORT OF CASE OF ABSCESS OF THE BRAIN.

R. L. JOHNSON, M. D.,† ROLLA, MO.

In bringing before you a description of a single case of abscess of the brain, I have the consciousness that although it may lack in detail, there is nothing added to embellish it—that it is not written either to establish or to conform to any theory of pathologist or surgeon, but as an offering of facts. It is only by observing and reporting facts accurately, that data are accumulated, from which general principles are deduced. No one surgeon has in his life enough cases of abscess of the brain to furnish all the data needed for the thorough establishment of rules of treatment. Therefore it becomes the duty of every practitioner to observe carefully and report accurately all cases coming under his observation. This becomes all the more a duty when we remember that these opportunities always imply suffering and risk of human lives and should, therefore, be carefully economized.

That rules of treatment are not thoroughly established, I find from the recent literature of the subject and also from conversation with a good friend of mine, an eminent surgeon in this city, who kindly told me I had not treated my case in the most approved style; for this I expressed my regrets, for had I done so, I might have been able to make my report more complete, by giving a description of the *post mortem* appearances.

On November 5th 1892, I was called to see William M. aged fifteen years.

*History and subjective symptoms*:—I was told that he received a blow upon the head, from an old lime-encrusted white wash brush, thrown at him, which had knocked him senseless for a while; that he had a slight dull headache and was somewhat constipated, and that he had been feeling badly for several days. I was only told of this accident after I had decided that he was suffering from a torpid state of the liver and bowels. Upon a careful examination of all objective symptoms, I found a slight depression an inch posteriorly to the external angular process of the frontal bone, a half an inch in length, over the portion contiguous to the sphenoid; the skin was not broken at all; the tongue was large and furred; his pulse rather slow and the temperature normal; he was dull and slow of speech, but perfectly intelligent; there was entire absence of paralysis, motor or sensory; his sight was good and the pupils responded equally and promptly to light. I gave a purgative and advised quiet for a few days and requested to be notified if he did not get well promptly. During the next two weeks he was not seen; he was at work—hard work—hauling stone. At the end of that time, after hard riding horseback, headache, which had troubled him some, became rather severe; he was given potassium bromide freely, which relieved it to a great extent. On the 30th, and on the 1st, 4th, and 9th of Dec., I saw him and found him getting thin; his tongue coating more and more; his countenance dull and heavy, his speech slow, cerebration perfect but slow, answering questions slowly but correctly; headache most of the time; there was no fever at any time. Although his countenance and general appearance suggested typhoid fever, there was never any rise of temperature or increased frequency of pulse. On the 15th his pulse was below sixty and halting, a hesitating pulse; his bowels would not move without an active cathartic; no paralysis; pupils always responsive. On the 15th I insisted on consultation with reference to trephining. Dr. T. J. Jones agreed as to the necessity of the operation, and Drs. Rowe and Carpenter were invited to be present and kindly assisted me.

A Y-shaped incision being made in the scalp, the trephine was applied to the frontal bone just below the temporal ridge and at a point corresponding internally with Broca's convolution. On attempting to elevate the depressed portion, it was found to be much comminuted, the fragments setting nearly at right angles to the plane of the skull; these fragments were carefully removed and the sharp edges of the skull were rounded off, the dura mater, which was was not torn and which was of a dark-red color, slowly rose up to its proper level, but did not bulge into the opening at all. To the touch it felt softer

†Surgeon St. Louis and San Francisco Railway.

than the brain, suggesting the presence of some fluid under it, but it was neither tense nor elastic. On consultation it was not deemed advisable to open it then as it could be done afterwards if he was not relieved. After the operation his general condition improved for a day or two; he became more cheerful and looked better, having lost the listless apathetic countenance. His pulse, however, continued as slow as before and his bowels remained constipated. On the night of the 19th, four days after the operation, it was observed that he did not use his left hand, which was not completely paralyzed, however, but so feeble that he could scarcely move it, while his grip was almost imperceptible. Paralysis of the left side of the face was now marked. Patellar reflex was absent (this was the case before he was trephined.)

There is now also a partial paralysis of the left leg. The pupils remain responsive to light. There has never been any impairment of vision or of power to move the eyes. On the 20th I opened the incision, which had healed by first intention, for about half an inch and pressed with the end of the grooved director upon the dura mater, and was satisfied that it was now tense and elastic. I then used a fine trocar and canula twice the size of a large hypodermic needle, pushing it downwards and slightly backwards (as he lay) one and a half inches before I reached pus. I then pushed in a straight bistoury and upon turning it pus flowed freely—"laudable pus." While it was flowing a rubber drainage tube was inserted one and a half inches into the wound and the pus continued to flow through and by it. The amount was estimated at three ounces, but it was not measured as it ran out freely on cloths and into the basin. The wound was dusted with iodoform; a thick compress of sublimate gauze was bound on; the drainage tube was brought through an opening in the compress and the end overlaid with sublimate cotton, and over all parafine paper. The relief from the operation was prompt. Before the opening of the abscess the pulse was forty-eight, and he appeared deaf and would neither answer nor move. In fifteen minutes he was reviving, and before I left the house, about an hour, he was smiling and talking freely and promptly. By the afternoon a remarkable change had taken place, instead of a shrunken, pale countenance he had some color; his lips were full and red and his pulse had gone up to eighty. The next day I attempted to syringe the abscess with a siphon, but there appeared to be but a very small cavity, some small clots, a little pus, and what appeared to be lumps of soft, broken down brain tissue. The next day only a little pus and bloody serum came away when I removed the tube, which I replaced. A few days after, as there was no discharge through the tube, I dilated the opening with a grooved director and got a teaspoonful of pus. From that time there was no further trouble of any kind; his pulse fluctuated from 65 to 82; he had no fever. Sordes, which I forgot to mention, cleared off; his tongue cleaned; his appetite became good and his bowels moved regularly without the aid of a cathartic. The changes in his physical condition appeared as remarkable as those in his nervous and mental phenomena. He rapidly progressed to perfect recovery and is now, one year after, at regular labor and apparently well, physically and mentally.

---

THE latest scare in microbes has been started by Professor Uffelman, of Rostock, who infected a letter with cholera bacilli, and put it into a post bag. When the letters were taken out, twenty-three and one-half hours later, the bacilli were still there. Bacilli were also found living on post cards twenty-four hours after infection. The micro-organisms were found to die rapidly when placed upon coins. A fly charged with cholera bacilli was afterwards placed on some beef. A little later the meat was found to be swarming with bacteria.—*Scientific American.*

---

WHEN a glass stopper sticks in the bottle, pass a strip of woolen cloth around the neck of the vessel and seesaw it backward and forward. This friction heats and causes the neck to expand, so that the stopper becomes loose. On this principle of expansion by heat a tight screw may be drawn from a metal socket with a cloth dipped in boiling water.—*Scientific American.*

THE truly great physician is one who never speaks ill of his medical brother. He is dead.—*Medical Record.*

# A STUDY OF THE URINALYSES OF 110 CASES OF INSANITY*

## ADMITTED TO THE MARYLAND HOSPITAL FOR THE INSANE FROM NOVEMBER 1, 1892, TO OCTOBER 31, 1893.

WARREN L. BABCOCK, M. D.,† CATONSVILLE, Md.

The systematic examination of the urine of the inmates of our public asylums and hospitals is a feature in diagnosis that has heretofore been neglected by the great majority of our asylum physicians. In those Hospitals where the examination of the urine, both chemical and microscopical, has been performed as a routine practice, the results have demonstrated the wisdom of the procedure. It is an unquestionable aid to a comprehensive diagnosis in many cases; a practice of precaution enabling the physician to adopt prophylactic measures before grave symptoms occur to warn him of the necessity for immediate therapeusis.

Much unfavorable comment has been elicited from those interested in urinary anomalies, by the fact that the physicians of our insane hospitals have persistently neglected the study of the urine of their patients.

About two years ago, Bondurant of the Alabama State Hospital, who has long insisted on a more comprehensive study of this subject, especially in its relation to Bright's disease, addressed a circular letter to Asylum Superintendents thoroughout the country, endeavoring to ascertain how many insisted on the examination of the urine of all cases admitted. He found to his surprise that only about a half-dozen in the country, made any effort towards a general examination of all cases admitted and that the great majority gave little attention to the subject, except in cases where the symptoms pointed to kidney disease and an examination of the urine seemed necessary to verify the diagnosis.

The writer has been unabled to find on record a single investigator who has written on the general subject of urinary anomalies of the Insane. It is true that a few have studied the causative relation of Bright's disease to insanity and reported isolated cases exhibiting urinary anomalies in general paresis and epileptic insanity, yet no reports have been recorded of a general chemical urinalyses of the insane.

In the tables given below efforts have been made to bring out all features of interest, both from a clinical and a chemical point of view, and notes have been made of all unsual cases. Abnormal ingredients and normal ingredients in excess will be briefly discussed and the clinical history of some of the cases presented by way of comparison with similar cases reported from other sources.

ALBUMEN. Considering each abnormal ingredient in the order of its clinical importance, albumen presents itself chief and foremost among those to follow.

The frequency of Albuminuria among the insane is a much disputed question. The reports recorded by writers on this subject are very contradictory to each other. Recent investigators, among them Dr. Christian of the Eastern Michigan Asylum,[1] Dr. Alice Bennett of the Norristown Asylum,[2] Dr. Tuttle of McLean, (Mass.) Asylum[3] and Dr. Bondurart of the Alabama State Hospital,[4] conclude that Albuminuria is very frequent among the psychoses and that bright's disease is a very prominent etiological factor in the production of insanity.

The last mentioned observer who has made a close study of the subject examined 1336 cases of various forms of insanity and found albumen in about 19.5 per cent. of all cases examined.

Dr. Amelia Gilmore of the Philadelphia Hospital for the Insane,[5] says that 25 per cent. of the admissions to the female department of the hospital give evidence of kidney disease by the presence of albumen and casts in the urine.

* From advance sheets of Hospt. Reports for 1893.

†Clinical Assistant, Maryland Hospital for the Insane.

1 Journal of the American Medical Association, March 23, 1889.

2 Alienist and Neurologist, Vol XI, No. 4.

3 American Journal of Insanity, April, 1892.

4 Journal of Mental and Nervous Diseases, November, 1892.

5 Journal of Mental and Nervous Diseases, August, 1893.

Only 9.9 per cent. of all cases admitted to the Maryland Hospital for the Insane during the past year had albuminuria, either of the pregnant or transient nature.

The variation in the percentage of cases affected, as reported by the observers quoted above, is explainable on the grounds that some forms of insanity contain a higher percentage of albumen in their urine, than others, and that the cases admitted and examined were plentiful in those varieties of mental disorder that are marked by the greater or less frequency of albuminuria.

On consulting table No. 2, on another page, it will be seen that the highest percentage of albumen was found in mania (12.1 per cent.) and epileptic Insanity (20 per cent.). These results are in accordance with those of many other observers but directly opposite those of Dr. Tuttle, as reported in the afore-mentioned paper. He finds his highest percentages in melancholia (40.2 per cent.) and general paresis (40 per cent.); compared with my results of 7.4 per cent. for the former and a total absence of albumen in the latter. This total absence in general paresis may be accounted for by the fact, that with one exception the urine was examined during the first stages of the disease. His conclusions in dementia agree with mine, both tables showing a trifle over 5 per cent. of cases of albuminuria.

Dr. Max Koppen[6] "finds that the presence of albumen in the urine of the psychoses apparently depends on the height or degree of the delirious element in the disorder."

Furstner, quoted by Tuke, found albumen in the urine of all cases of delirium tremens and demonstrated that the amount was directly proportioned to the intensity of the delirium.

My observations are directly in accordance with the above statements.

Thus it is found most frequently in acute and acute delirious mania and all psychical states attended with delirium whether of centric, excentric or toxic origin. Delirium is essentially an aggregation of psychical manifestations of a reflex nature, attended with exhausting symptoms, such as insomnia; anorexia; great restlessness and often slight fever, altogether presenting all the factors essential to increased tissue waste. The kidneys, overworked by increased elimination, undergo structural changes which are enhanced in degree by the high vascular tension and the arterial changes consequent on impoverished nutrition.

The highest percentage of albumen in the list was found in epileptic insanity (20 per cent.). The specimens examined were taken at random and usually during the interval between the paroxysms. By repeated examinations in one case it was noted that the amount of albumen was materially increased directly after the paroxysm.

Huppert[7] goes so far as to claim "that albumen appears in the urine of every epileptic soon after the paroxysm and that the amount depends on the severity of the convulsions."

Voison and Perron[8] found albumen in 50 per cent. of cases of "grand mal" and 100 per cent. of cases of status epilepticus.

In opposition to the above statements, Dr. Wm. Browning,[9] in an article on the epileptic intervals says "any special frequency of albuminuria in epilepsy has been disproved."

My examinations have convinced me that albuminuria is very frequent among the epileptic insane and that the amount of albumen passed with the urine is, in most cases, directly proportioned to the frequency, duration and intensity of the paroxysms.

The physical symptoms of the ten cases containing albumen vary greatly. Three of them are evidently chronic interstitial nephritis as shown by the following brief clinical histories.

No. 7. Mrs. E. A. F., aged 55 years, recurrent mania. When admitted in Dec. '92 was unable to walk. Physical examination revealed apparent cardiac dilatation with compensatory hypertrophy; cardiac mitral regurgitant murmur; atheromatous vessels; abdomen enlarged and distended with fluid; lower limbs œdematous and varicose, their surface covered with chronic superficial ulcers, and liver enlarged. One week after admission laparotomy was performed by Dr. Rohé and the hospital staff. Two gallons of fluid was evacuated from the peritoneal cavity.

6 American Journal of Insanity, Vol. XLVI, No. 1.

7 Tuke's Psychological Medicine, Page 1348.

8 American Journal of Insanity (abstract), Vol. XLIX, No. 1.

9 Journal of Mental and Nervous Diseases, Vol. XVIII, No. 7.

Recovery complete with improved mental condition. Albumen still present in small quantity.

No. 32. Mrs. E. K., aged 75 years, dementia. Plethoric habit; lower limbs œdematous; atheromatous arteries; hypertrophied heart and high arterial tension. Albumen constantly present.

No. 98. John J. D., aged 78 years, senile dementia. Died two months after admission. Urine contained both albumen and sugar. Specific gravity 1043. This case was unusually interesting from a pathological standpoint. It will be further discussed under the caption of sugar on another page. The post-mortem notes read as follows:

KIDNEYS. Both enlarged and very firm; cortical substance much diminished; capsule adherent; large cyst on right kidney containing three ounces of fluid; smaller cyst on left organ.

HEART. Greatly hypertrophied, especially the left side. Valves normal. Calcareous plates in aorta; and evidence of general arterio-sclerosis. The other cases present no special features of interest. No. 45 is a case of lactational insanity in which the albumen disappeared as improvement ensued. No. 91 is a case of epileptic insanity which presents the usual features of this form of insanity. Nos. 8, 10 and 66 are apparently cases of the so-called "Albuminuria of Adolescence," or as termed by other writers "Cyclic Albuminuria." These three cases closely resemble each other, the amount of albumen being slight and variable in quantity in each. The specific gravity, color and quantity of urine passed daily closely approximates the normal. The remaining two cases can doubtless be classed among those known as functional or intermittent albuminuria. Neither manifest any other symptom of kidney disease than the occasional presence of a slight quantity of albumen in their urine.

SUGAR. Sugar was found in the urine of four of the 110 cases. This high percentage (3.6 per cent.) is largely in excess of the frequency of glycosuria among the sane. The tests used to demonstrate its presence were: Fehling's and Haines' cupric sulphate; Boettger's bismuth; and the Picric acid test.

Several manifestations of the psychically diseased readily account for the fact that diabetes is a frequent concomitant of insanity. Among the most prominent may be mentioned the following:

A. Nutrition disturbed.

Prolonged and intense mental excitement and emotional disturbance, insomnia, anorexia, the ever varying physical strain that the mentally diseased economy undergoes, causes disturbed and impoverished nutrition as well as nervous degeneration in cases which are usually of a neurotic temperament from heredity.

B. Organic cerebral disease.

The special frequency of gross cerebral disease in the psychoses. Glycosuria due to disease of the brain is often met with in hospital practice. Frerichs collected thirty cases of brain disease giving rise to the excretion of sugar in the urine. Injury or tumors of the medulla in man and animals have demonstrated that a diabetic centre exists in the medulla near the floor of the fourth ventricle. Bernard located its exact position by a few well executed experiments on animals. Recklinghausen quoted by Tuke found sugar in the urine of a case of tumor of the floor of the fourth ventricle and Dompeling, quoted by the same authority, in a case of tumor of the pons and upper third of the medulla.

C. Congestion of the nervous centres.

The great motor restlessness of the maniacal insane is thought to be due to congestion of the motor tracts of the cord and motor centres of the brain. Pavy claims that the close proximity of the Bernard's Diabetic centre in the medulla to the over-functioning motor tracts would lead to stimulation of the latter, and the appearance of sugar in the urine. Diabetes due to this cause differs from that originating in disordered nutrition by the absence of progressive emaciation, voracious appetite, intense thirst and rapid course.

Judging from the frequency, in insanity, of these three-mentioned factors in the etiology of diabetes, it would seem that Glycosuria would be a frequent concomitant of mental disorder. My analysis of 110 cases seem to show that diabetes is 50 per cent. more frequent among the insane than any other class of the population. A more extensive urinalysis is necessary before any definite statement can be made on this subject.

The mean specific gravity, of the urine, of the four cases mentioned, was 1038.5.

Briefly analysing these cases, we find them as follows :

No. 59. M. J. K., aged 50 years; Acute Mania; physical health good. Urinalysis during the mania revealed the presence of sugar in large quantity, and a specific gravity of 1048. On subsidence of the mania sugar disappeared and has not since returned. The glycosuria in this case was doubtless due to the last-mentioned cause enumerated above, namely, temporary congestion of Bernard's centre in the medulla, and tends to advance the latter theory as a common cause of transient glycosuria among the insane.

No. 98. John J. D., aged 98 years. (See case No. 98 above).

The only symptoms of diabetes in this case was the presence of sugar in the urine. His physical health was good and his body well nourished. The post-mortem clearly demonstrated that the glycosuria was of cerebral origin. The brain was found to be of average size and weight; dura was adherent to calvarium; ventricles enormously dilated and filled with fluid; the floor and sides of the fourth ventricle were infiltrated and greatly thickened; right temporo sphenoidal lobe softened and broken down; frontal lobes atrophied, especially the right, which was marked on the surface by a recent hemorrhage; medulla soft and anemic. The presence of sugar in the urine of this case was apparently due to the involvement of the diabetic centre in the infiltration of the floor of the fourth ventricle, together with the apparent degenerated condition of the medulla.

The other two cases (Nos. 119 and 120) present no special features of interest.

It will be noted by a reference to the tables that two cases (Nos. 35 and 99 in the column under sugar are marked with an interrogation point. On examining the urine of these patients for sugar with the Cupric Sulphate tests, the reaction indicated a large quantity of sugar. Boettger's bismuth and the picric acid tests failed to verify this fact, and other reducing agents were indicated as the probable cause of the reduction to cupric oxide. The presence of chloral in the urine of these patients, was suggested by the fact that they both were taking or had recently taken bromidia, which largely depends on chloral for its sedative action.

Witthaus [10] says that when taken continuously or in large doses chloral appears in the urine, and acts toward the cupric sulphate tests similarily to sugar. In fact many chemists use Fehling's solution as a test for chloral, in instances where the co-existence of sugar is negated.

PHOSPHATE IN EXCESS. An excess of earthy phosphates was found in 15.4 per cent. of all cases chronicled. These cases were so distributed throughout all varieties of insanity that few inferences can be drawn from its presence. Some writers have attempted to show the especial frequency and significance of an excess of earthy phosphates in cases of general paresis. It was present in 16.6 per cent. of my cases. This low percentage, compared with the greater frequency reported by other observers, I account for as follows: Of the six cases examined, all were in the first stages of the disease except one, and that single patient was the only one whose urine contained an excess of phosphates. Therefore I am inclined to the view that earthy phosphates do not appear in excess in general paresis until the latter stages of the disease, when decline is rapid.

URATES IN EXCESS. Urates in excess were found in 6.2 per cent. of all cases examined. The murexide test was used to demonstrate their presence. Of the seven cases containing urates, four or 52.2 per cent. were found in the manias. I can find no literature on this part of the subject, therefore no significance regarding its especial frequency in mania can be drawn until a series of cases are reported

BILE PIGMENT. Bile pigment was found in the urine of two female patients (cases Nos. 41 and 45) and its presence could not be accounted for from a physical standpoint, as both patients were in fair health at the time the examination was made. Gmelin's and Ultzmann's tests were used to demonstrate its presence.

Both patients were taking iron daily when the examinations were made, and in the absence of other causes, that fact I consider sufficient to account for its presence. To demonstrate this view, the administration of iron was temporarily discontinued in one case, and after the lapse of one week the urine again examined for bile pigment. As anticipated no bile was found on repeated examinations.

10. Manual of Chemistry, page 202.

That the iron caused an increase in the hæmoglobin of the blood and the latter a corresponding increase in the amount of bile pigment seems evident, the excess of bile pigment being eliminated with both fæces and urine.

SPECIFIC GRAVITY. The average specific gravity of the urine of the 110 cases was 1024.5, that of the females being 1023.5, while that of the males was 1025.5.

Dr. Gilmore, in the paper mentioned in another part of this article, says that urine of low specific gravity is most frequently found among the insane. My tables show that the mean specific gravity is much above the normal and varies according to the variety of insanity examined. In order that these cases may be readily studied I subjoin a table giving the average specific gravity of the urine of the several varieties of insanity.

Compared with the above, Tuke reports of the examination of the urine of 248 cases of insanity from the Bethlem Asylum. He found the mean specific gravity in cases of Mania to be 1026, of Dementia 1020, of Melancholia 1025, and of General Paresis 1021. The mean specific gravity of 248 cases examined was found to be 1025.5 while that of my series of 110 cases was 1025.6.

Rigby, quoted by Tuke, found a high specific gravity (1030) in the urine of Melancholiacs and a low specific gravity (1015) in the urine of cases of Dementia.

Thus it seems fairly demonstrated that the amount of normal and abnormal solids in the urine of the insane is over and above the total amount present in the urine of those who enjoy mental health, instead of below the normal as reported by a few observers.

SPECIFIC GRAVITY TABLE.

SIR BENJAMIN RICHARDSON, in an address on "Athletic Life," says that abstinence from alcoholic fluid is absolutely necessary. "As long as you are in course of training, don't touch the hurtful thing. It will undermine all the qualities on which you depend for success, will injure your precision, your decision, your presence of mind and your endurance."—*Pub. Opinion.*

## SOME INTERESTING SURGICAL CASES.

MARIE B. WERNER, M. D., PHILADELPHIA, PA.

I desire to report these surgical cases and study the tumors, because they present some particularly interesting features.

CASE I.—A multiple fibroid, very readily diagnosed by the many irregular nodules, clustered around the main tumor. The patient, who was sent to me by Dr. Ella S. Webbs, of Oxford, Penn., had suffered from hemorrhages and the usual pressure symptoms, all of which made it impossible for her to work; the result of the operation was all that could be desired.

These tumors are sometimes benefited by the simple removal of the ovaries and tubes, with the hopes of depriving it of its nutrition and inducing thereby a shrinkage of the mass, as well as permature menopause. This treatment was adopted after observation had taught that natural menopause had sometimes induced a cure. In this case the ovaries were so bound down that it became necessary, in order to give the desired relief, to remove the entire mass.

The operation of hysterectomy in this special class of fibroids has two important advantages; by the removal of the entire uterus, the patient no longer is in danger of any retrograde (sarcomatous) changes which, we know, often take place in this abnormal tissue; and again where there are fibroids near the mucous surface which even after careful and complete removal of the appendages have given rise to dangerous hemorrhages and necessitating further operative procedure.

CASE II.—Gives us evidence that fibroid tumors of the hard variety may grow even after the menopause has been established.

The patient was sixty years old, had five children, no miscarriages and passed the menopause at the age of fifty-two. There was no flow for two years, when suddenly a profuse hemorrhage occurred, which was repeated in a few weeks. An examination revealed an enlarged globular uterus and a small atrophied cervix; the fundus of the uterus reached a little below midway between the pubis and umbilicus. Various medicines and treatments were used, with but partial success. The intervals between the hemorrhages were longer, but the loss of blood was more profuse; in fact, on one occasion the loss in a half hour was so great as to produce syncope. The hemorrhages came on without pain or warning. In one instance the patient was sitting on a chair and remarked that she must have sat in water, but upon looking found that a hemorrhage had suddenly come on, her clothes and the floor were stained with blood; in the recumbent position it was scarcely possible to feel her pulse for some time. This was about the last severe hemorrhage before the operation. She felt that she was getting weaker, and was beginning to feel unable to attend to her household duties as formerly.

An examination showed that the mass had grown to about twice the size it had been on a previous examination, two years before. It was wedged down in the pelvis and almost on a level with the umbilicus. After consultation with Dr. J. Price, the patient, herself, fixed upon the time of operation, which was performed in January,'93, after some time of preparatory treatment. Assisted by Dr. J. Price, I removed the tumor which was wedged down in the pelvis, adherent in some places, the ovaries and tubes, particularly the right tube, being supplied with immense blood vessels.

In making the stump, we found the cervix, as well as the whole uterine cavity, filled with a soft spongy mass, suggesting cancerous changes. Closer investigation of the tumor, after the operation was completed, revealed a very large uterine cavity, the distance between the two cornua being six inches, not including that part of the canal inclosed in the stump. The anterior wall of the uterus was thin enough to give the definite outline, externally, of the finger within the cavity, suggesting the danger of the use of intra-uterine electricity or the curette, both of which, with a solid resisting tumor in the posterior wall would have found a ready exit, after the exercise of even a moderate amount of pressure, with an unavoidable resulting peritonitis. Again a careful examination of the tumor will show you the enormous blood vessels, especially near its mucous surface, their open mouths showing the daily danger of a fatal hemorrhage. This tumor, without doubt one of the hard variety of fibroids, increased in size during

the last four years. We are taught, and various operators have agreed, that the simple fibroid ceases to grow and even decreases after the menopause has been established. We have here a case in which there is undoubted exception to the above theory.

Case III. That of a young girl aged twenty-eight, who had been suffering with hemorrhages and pain during the last two years. She submitted to various kinds of treatment, electro-puncture among the others, which latter, unfortunately, had produced some difficult adhesions. Examination showed a uterine tumor reaching midway between the pubes and umbilicus. The cicatrices from electro-punctures could be easily felt; both lateral pelvic spaces were painful on bi-manual pressure. The patient was anæmic in the extreme, her hands and finger nails waxy in color and almost transparent. The tumor as it came to sight after incision was made, had the characteristic appearance of a myoma, so much so that my assistant, Dr. Elliston J. Morris, inquired if I was absolutely certain that the patient was not pregnant. The tumor was removed with difficulty, since it had been partially twisted on its axis from left to right, and become adherent in that position, no doubt by the electro-punctures, for the scars were found on that side. With the united strength of my assistant and the screw, we were at last enabled to enucleate it. The left ovary and tube were fixed behind the uterus, while the right appendages were floating free above the pelvic brim.

This case will enable me to show you, very clearly, the formation of a pedicle, which has always been the most interesting and important part of the extra-peritoneal method. The tumor having grown rapidly, its peritoneal covering was thoroughly stretched; it became necessary, after having adjusted the wire loosely, to make a circular incision into the capsule from four to five inches above the line of the nœud. This immediately retreated close to the wire, and the bladder having been drawn up, by the rotation of the tumor, was thus saved from being injured. The operation was soon completed after making the usual toilet of the peritoneum, and taking the peritoneal stitch on each side of the stump. A drainage tube was placed, and the incision closed.

This case again shows an enlarged uterine cavity measuring four inches between the cornua. Some granulations can be seen on the mucous surface.

Case IV.—Is one of unusual interest, of uterine cancer removed through the vagina; interesting from the fact that through the patient's persistent refusal of an operation I have actually seen its devolopment. Three years ago she came to me, suffering from pelvic pain, due to pyosalpinx. I advised an operation to which she submitted, made a good recovery and would hear of no further operation, which was actually called for on the large, unilateral tear of the cervix. She occasionally appeared at my office for local treatment, usually after having had a severe hemorrhage or some pelvic pain. The uterus being freely movable, I knew the pelvic pain was not due to any adhesions. The appearance of the cervix, enlarged, congested and mottled, showed me that I could look for the trouble there. Several weeks treatment, consisting of depletion and tampons, would usually relieve her for as many months, always to be followed by a return of the former appearance and symptoms.

All suggestions of operation for any radical treatment remained unheeded. At one time I succeeded in removing a small portion of the cervical tissue and examined it carefully under the microscope. It showed distinctive cancer cells. The patient again remained deaf to all good advice and I saw nothing more of her for about six months; when she came she reported having had hemorrhages and suffering now from a constant offensive, viscid discharge. She then permitted me to remove the uterus. As you see the uterus has been entirely removed, but the cancerous degeneration seemed to have proceeded on to the right broad ligament. This operation was done October, 1892, the patient is still living, but is no doubt suffering from a cancerous degeneration of one or more of the internal organs; she has a slight inoffensive discharge from the vagina.

This case taught me that early operations will give a better chance to the patient than any other known treatment.

Case V.—Is a case of sarcomatous kidney, removed from a child two years old, August, 1892. It weighed, some hours after removal, 8 lbs. and the measurements were 8¾ by 5½ inches; cicatrix 6½ inches.

The child had the appearance of a

little skeleton straddling a tumor. The operation was done more to relieve the pressure symptoms she was suffering from, thinking she had some abdominal effusion, but it became necessary to remove the kidney after the incison was made and strange to say the child got well. There were many things against which she had to struggle. The operation was done in a four-roomed house in a small street, a railroad about a quarter of a square away with all its accompanying dust and dirt, and the thermometer in the 90's, so that I was placed in a position of choosing between two evils after the operation—to let the child remain in the hot room or to place it in the coach and set it out in the shady places on the street.

There was several interesting points about the operation; one, which necessitated peeling off the adherent bowel resulted in a tear of its mesentric attachment of about six inches in length. This was carefully sutured and a voluntary movement three days after the operation seemed to be painless and had absolutely no sign of blood, proving its union. Urination was voluntary during the first night, with but slight amount of blood present which was probably due to the cutting of the ureter. I have always regretted that I have not had a picture of the child as she was before the operation. Of course there is always a sequel to these operations. One usually looks for a return and it came in this case, although the child became apparently healthy. The return was located in five of the retro-peritoneal glands, also a growth in the pancreas similar to the one on the kidney. The right kidney was slightly enlarged otherwise it seemed normal.

As you will see, this tumor originated in the corticle substance; the pancreas was attacked in the same way. The patient died on December 13th; the return having shown itself three weeks previously.

In a collection of thirty-one nephrectomies for abnormal growths of the kidney occurring in children at or under twelve years of age, we have sixteen recoveries and fifteen deaths, making an immediate mortality of 48.4 per cent.

Of the sixteen there were eight who succumbed to a return of the disease, five at or under four months (one of these at eleven weeks), three at or under eight months. One was reported to have died one and a half years after the operation; cause not stated. In one no return after three months, another after four months, and four not stated.

**Tuberculin as a Test for Tuberculosis in Cattle.**

Probably few physicians are aware of the enormous practical value in the animal industry of tuberculin; that is to say, if the position taken by the New York and other State Boards of Health regarding it is correct. A gentleman who has a valuable herd of thoroughbred cows writes us that twice within the last six months his herd has been examined by competent veterinarians and pronounced healthy. A third examination, however, with the aid of tuberculin, caused a condemnation of over one-half the herd. He adds:

The New York State Board of Health is killing by the hundred, animals condemned by diagnosis with tuberculin, and the State is paying full value for them. The veterinarian says that the autopsy shows the diagnosis to be correct in every case. He says also that it is impossible for the best veterinarian to discover tuberculosis by physical examination except in extreme cases. My herd is apparently in splendid condition. Breeders do not know of its existence in their herds. They let a cow remain in the herd until she is unquestionably tuberculous and then remove her, but she has then already infected the herd. A temperature of 103° F. condemns the cow. In a herd of Jerseys, at Troy, of eighty head, he has killed thirty-three, and will kill twenty more of them this week. Autopsies are held in the presence of physicians and veterinarians. There have been 15,000 tests with tuberculin in England. New York evidently believes in this kind of diagnosis, and will probably have to pay $500,000 to eradicate tuberculosis. The veterinarian says the State is full of it in herds both of thoroughbreds and common cows.

We understand from other sources that the State Board of Health fully believes in the certainty of tuberculin diagnosis. Through its means it has been discovered that some of the best bred herds, supplying high-priced milk, cream and butter, are infected.—*Med. Rec.*

## LARYNGISMUS STRIDULUS FOLLOWING BULLET WOUND IN THE ARM.

J. W. Irwin, M. D., Louisville, Ky.

A few years ago I had under my care a man twenty-two years of age, the son of a hardware merchant, who while handling a pistol one day accidentally discharged the weapon, the bullet entering his right arm just under the anterior border of the deltoid muscle near its insertion, right over the region of the nerves leading down from the axilla. No notice was taken of the bullet, or could it be found, as it was buried under the muscular surface; the external wound healed without any trouble. Four months afterward, he was taken with the most intense form of croup. It was not the season of the year when croup usually occurs. (It looked more like laryngismus stridulus.) I was sent for in the initial attack, and administered remedies with a view of relaxing the condition. Medicines did not seem to have any effect unless I kept him under the influence of chloroform—ether relaxed it even better than chloroform. I treated him several days for this affection of the throat, and I could discover nothing but a spasmodic condition to treat. He could not drink without bringing on an attack; could not change his position, could not laugh, could not talk without bringing on a most intense form of spasmodic croup or laryngismus stridulus.

I knew nothing of his former injury at this time—later he told me that he was shot in the arm some months before; I then began to look for some reflex irritation as the cause of the trouble. Upon inquiry the history as above related was elicited. I made an examination of the wound. Nothing could be seen but a very small cicatrix slightly depressed, and after lifting the muscle from the bone with my fingers, I thought I could feel a little hard substance. I asked him if the bullet had ever been removed, and he stated that the physicion who attended him had never been able to find it. That it occasioned him no trouble up to that time, and so far as he knew the bullet was still in his arm. There was no sensitiveness to call attention to the cicatrix. So far as references to the wound is concerned, the patient did not know he had a bullet in his arm. I then made a further investigation, and found the bullet which had lodged in the deltoid muscle near its insertion. It had become encapsulated, and was about the size of an hazel nut. I at once suggested the removal of the bullet, believing that it might be the cause of the reflex trouble. He accepted the proposition, and the operation was easily and quickly done. The second day after the removal of the bullet, the spasmodic trouble disappeared, and four years afterward it had not returned. I would not have been surprised in that case to have seen epilepsy.

## THE ROLE OF THE BLADDER DURING CHILDBIRTH; RETENTION OF URINE.

The form of the bladder in the woman differs from that in the man. Instead of being ovoid with a median distension, it is more flattened from before back and is not symmetrical; its right half is larger than its left. Its base assumes a much greater lateral distension on account of the disposition of the vagina and the pelvic organs in general. This flattening and this enlargement are more marked in the multiparous women than in the primiparæ. Haller admits that this enlargement is due to the pressure which the gravid uterus exercises upon its base. In consequence of repeated pregnancies this lateral expansion will become more and more marked. Barlow attributes this special form less to the effects of the pressure of the gravid uterus than to the movements and the rubbing which the uterus and its appendages exert upon the bladder. Ouimet believes that both causes are active. During the first months of pregnancy, the form and the connections of the bladder change but little. The sinking of the gravid uterus together with its weight, on account of its firm attachment to the posterior wall of the bladder, prevent elevation of this organ distended by urine. Its antero-posterior expansion not being permitted, in proportion as the urine accumulates the bladder can expand only in the transverse diameter. When the uterus on account of its volume is obliged to rise out of the pelvis and to take its place in the abdominal cavity still the same conditions hold; its antero-posterior expansion is always hindered by the uterus; its lateral expansion only is easy. It is at this period, also, that there is produced an alteration in the situation of the urethra. It forms normally a slight curve with its convexity below. If the distended bladder drags itself upward, the curve increases, if it forces itself downward, it diminishes or disappears. There is also a change in the curve in proportion, as the vagina is stretched during pregnancy. At the end of the pregnancy, the capacity of the bladder is, in primiparæ, diminished on account of the low situation of the inferior segment of the uterus and the fetal head, and in multiparæ, quite to the end of pregnancy, the result is similar, although much less marked on account of the sinking of the uterus. In some cases of pregnancy (pendulous abdomen) the bladder may be compressed from above downward, and consequently show a tendency to the formation of a perineal or vaginal hernia. A retention of urine exists then, and a large cystocele appears. At the beginning of labor, important changes may be observed. The urethra is lengthened, and the bladder is elevated above the pubis. This modification in the situation of the bladder is produced in order to avoid a retention of the urine. "The urinary bladder," says Smellie, "in the pregnant woman near to term, is often so pressed upon by the uterus that it can only contain a very small quantity of urine." From a study of the subject of the retention of urine, during and after child-birth, Ouimet has formulated the following conclusions:

1. Retention of the urine during confinement and delivery, may produce results so grave for the mother and child that every accoucheur called to attend to a women at the beginning of labor, should at the first disengaged moment, inquire as to the time that has elapsed since the last micturition and as to the manner in which micturition was accomplished during pregnancy.

2. The accoucheur should not be satisfied with the woman's replies, but should practice a careful examination of the genito-urinary organs.

3. A small quantity of urine retained in the bladder will suffice to cause grave disorders. The bladder should be emptied naturally or artificially, at the time of confinement.

4. If it is always proper to empty the bladder, even in normal confinements it is of the greatest importance to empty it when it is necessary to perform an obstetrical operation—version, the application of the forceps, Cæssrean section, etc. —Ouimet in *l' Union Medicale du Canada*, July, 1893.

—D.

## A CONTRIBUTION TO THE THEORY OF EPIDEMIC NIGHT BLINDNESS.

O. Walter (*Arch. f. Augenheilkund* xxvii) observed in the Ural region, during the years 1889–92, 269 cases of night-blindness; 197 among men and 72 among women. The history of these patients was that there were no prodromal symptoms; the sight was suddenly lost on a certain evening. The disturbance in vision began in the centre of the visual field, spreading centrifugally. Shortly before or after the rise of the sun, the sight again suddenly returned. The grade of blindness in the presence of poor illumination varied in different cases.

Ophthalmoscopically there was in but few cases an appearance of dimness in the region of the papillæ. The duration of this disease was variable, and returns occured in 78.8 per cent.

In places where sanitary conditions were poor, this epidemic occurred early in the spring, and attacked persons of all ages; an increase of numbers being noticed among those who suffered from lack of good sanitation. A deficiency in nutrition could be regarded as a predisposing element, to which could be added certain direct causes. No psychical overexertion or dazzling elements, as some other authors have described, were noticed in these cases; in all miasmatic influences were present.

The treatment consisted in nutritive diet, and internally, cod-liver oil with strychnia. —W.

### Abdominal Hysterectomy.

Dr. L. G. Richelot reports (*L'Union Medicale*, 1893) twenty-one hysterectomies with two deaths. Great importance is placed upon the following points in the technique. 1st. The stump is carefully sewed with silk. 2d. A peritoneal flap having been previously prepared, is secured over the surface of the stump. 3d. The stump is carefully seared with the cautery before being covered. Total extirpation of the uterus has not yet received his approbation.—*Centralb. f. d. Med. Wiss.*, No. 45, 1893. —W.

### The Dublin Conjoint Examinations.

The returns of the October examination of the Colleges of Physicians and Surgeons in Ireland show a decrease in the number of candidates as compared with last year of 149 to 122. The examination was, on the whole, excessively fatal to candidates, the rejection percentage being 54.0 as compared with 42.2 for the same examination last year. The "mortality" was greatest in the second and third examinations, in which the rejection rates were 60.9 and 63.6 as compared with 38.1 and 58.2 for the same examinations of the same period last year.

The committee recommend to the Colleges:

(*a*) That a numerical system of marks ranging from 0 to 10 be substituted for the "judgment" system at present in use.

(*b*) That a uniform standard of 50 per cent. be the passing mark in all subjects, and in all examinations.

(*c*) That in deciding as to whether a candidate has passed in any subject or not, the marks in all the divisions of the subject—written, oral, and practical—be considered together; provided, however, that bad answering in the clinical portion shall not be compensated for by excellence in the other portions of the subject.

At the Preliminary Examinations held in November and December, the rejection percentage was 44.3, against 47.4 at the same examination last year. The entries were 89 as compared with 96 last year. There seems to be a curious variance in the quality of the candidates at the two examinations of the present year, the rejection percentage of the November examinations have been 57.7, while that of the September examination was only 38.7. On the whole it will be observed that the Irish Conjoint Examinations do not err on the side of softness. Whether it be that candidates are of inferior quality, or that the examination is unpractical and excessively severe, the fact remains that the average candidate runs a better chance of getting through his examinations in either England or Scotland than in Dublin. Neither of the other divisions of the Kingdom show so high a rejection percentage as Ireland.

## EDITORIAL.

### REORGANIZING A COLLEGE.

The Jefferson Medical College has long sustained a reputation as one of the best medical institutions in the United States, and to-day all things considered it has no superior in this country. The men comprising its present faculty, are worthy successors of those teachers of the past whose abilities created the reputation of the college, and whose fame is inseparable from the fame of Jefferson. Such men as Parvin, Keen, Da Costa, Forbes among the older members of the faculty, are men of world-wide reputation and authority, both as teachers and practitioners. Among the younger members such names as Dercum, De Schweinitz, Hare, Montgomery have more than a local significance and assure the maintenance of its reputation at the same high level that has existed in the past and now exists; and in all probability buds of promise will be developed from among the sucklings of the faculty.

If not always the first to institute movements towards higher medical education, Jefferson has never been the last to adopt improvements. The college has a large and enthusiastic alumni association, which possesses what few such associations do possess, a considerable influence with the powers that manage its alma mater. It was probably due to the influence of this association that the college has recently adopted the four years' course of study to obtain a diploma.

At a meeting held last week, the Association adopted resolutions calling upon the Board of Trustees for further modifications in the organization of the college, which will undoubtedly increase its effectiveness. The first of these calls for the abolition of the fee system of paying the teachers and a substitution therefor, of fixed salaries. Such action would tend to equalize the compensation of the members of the faculty, and would at once cut off the greatest obstacle to enforcing a higher standard of medical education, for the question of increasing or decreasing income would have no weight in considering the fitness of an applicant for matriculation. The require-

ments for admission could immediately be strictly enforced, and if desirable, raised, and would at onee exclude a class of aspiring novitiates, whose presence in an institution of learning can be accounted for only on the supposition that they can pay admission prices. This would at once conserve the reputation of the institution for the quality of its product and for the quantity of its honesty.

A second resolution was adopted, requesting the Board of Trustees to appoint a member of the faculty as prevost, and place in his hands certain high powers and privileges, as for instance, meeting with the trustees, recommending additions, etc., suggesting candidates to fill vacancies. In general, to be an authoritative working-head for this institution, with the extensive powers committed to similar officials in other institutions that we wot well of. The appointment of such an official is fraught with danger to the ultimate success of the institution, even when limiting the power placed in his hands. While placing unlimited power in any one person's hands is practical suicide or slavery. History need not be searched for examples to prove this statement. Nor are the causes of disaster hidden from view. The centralization of power is of benefit up to the point where it places definitely responsibility for the exercise of powers, but when carried to an extent that makes power autocratic, responsibility practically ceases and the exercise of power implies slavery on the part of all coming within its province.

Of course it will be claimed no such absurd proposition has been made, and that there is no intention to establish a dictatorship. Neither did the fabled tailor intend to admit the entire camel when he allowed him to put his nose in the door. The advantages of a working head for an institution are obvious, but the disadvantages of that head becomimg swelled are sufficiently great to deserve consideration. If great power is to be entrusted to any one person, he must be possessed of certain characteristics to perform the duties required of him. His individuality must be decided enough to enable him to formulate a definite policy. His executive ability must be great enough to successfully carry out his policy. He must combine the wisdom of the serpent with the harmlessness of the dove. He must be all things to all men. He will receive the support of the authorities that established his position—at least he will receive it at the outset, later on he will compel it. The greater his ability to fill the position, the greater danger is he to the final success of the institution.

Among the eminent men constituting the faculty of Jefferson College, we doubt there is one who, placed in such a position, could command the hearty support of his peers in the faculty. Dissensions invariably arise among men seeking the same end, but thinking for themselves. Where the will of the one is paramount, obstacles to his policy must be removed, and opponents retire, or suffer the infliction of an emeritus position. Policy will not allow a recurrence of like opposition if preventable, and the dictator installs a puppet of his own in the vacant position. The dictator's position is thus strengthened at the direct expense of the institution. Retirement is the fate of every man who presumes to think for himself and has the courage of his convictions.

A medical college in pantomime, whose puppets dance at the bidding of any one person, is a sorrowful spectacle for the last decade of the Nineteenth century.

A one-man medical college is always a 'one-horse' institution.

THE REPORTER is interested in this matter in as far as the cause of medical education in Philadelphia is concerned, and it begs to commend to its Jefferson friends that saying of Demosthenes: "The end of wisdom is consultation and deliberation.

## THE MEDICAL BUCCANEER.

Before the days of steam-ships, and indeed until the early part of the present century, the high seas were everywhere infested by bands of pirates in quest of prey.

When they sighted a prize they set sail straight for it, and when the attack was ordered no quarter was asked and none given.

Those daring characters have always been painted by historians in the blackest colors. But after all, they were not without a redeeming trait, for, when captured they expected no mercy. They were a thousand times more manly than the modern, *medical* buccaneer.

To talk of amending codes, or instituting reforms, or improving the status of the profession while this insatiable gormand is allowed unfettered liberty is a travesty on reason. He plays his part in manifold ways. He often roams in high places, and may even wear a professor's gown. He looms up at medical conventions and indeed, may even be an author of no mean position. He is always clamoring for reform; he wants to reform the code, let down the bars and clear the way so that his pilfering career may be unhampered. His neighbor stands in mortal terror of him, because, he well knows, that should he be required to call him in consultation, the new arrival would quickly oust him and cooly take possession himself. He performs impossible operations and always cures every case, and the unsuspecting, simple-minded, honest plodder, as he reads his statistics, is quite overcome with amazement and admiration. He has a sneaking way of advertising. To go into the regular column of the quacks, would be to mix with the common herd; moreover it is highly expensive; therefore he has himself *interviewed*, or one of his helpers will see to it that, while the great man speaks, full stenographic notes are taken and the thing, highly colored, will be spread broad-cast in the early morning press.

The drag-net of the pirate is so far spread out, that he leaves almost nothing for the honest plodder. From year to year he becomes more and more bold, and finally, having duped and bulldozed his professional brethren, he turns his attention to lay people before whom his hideous hypocrisy is supported by consummate strategy. He wants to raise funds for a ward "for the poor, you know," run *soirees*, parties, etc., until a necessary sum is wrung out of the pockets of the unsuspecting. Then he suddenly blooms out a specialist, and now that he is safely entrenched behind his own walls, in his zeal for patients his audacity is villianous, for through the mails, he is a constant intruder, incessantly appealing to practitioners to send to him that which they themselves depend upon for their living.

Let every independent, self-respecting member of the profession rise and stamp out this scorpion. He is the bane, the curse and blight of a profession, which without him has a career of usefulness and prosperity before it.

---

### The Effect of Urine, Normal and Pathological, on the Heart.

Lusini (*Arch. di Farmacol. e Terap.* Fasc 19, 20, 21, 1893) has studied the effects of normal urine when applied direct to the heart of the frog or toad, comparing it with that produced by the urine of jaundice, tuberculosis, nephritis, scarlatina, measles, and pneumonia. He concludes as follows: (1) Normal urine always causes an increase in the extent of the individual heart beats. (2) The urine passed in disease produces peculiar toxic effects directly proportional to the increase of urea, salts, colouring matter, extractives, etc., as well as to the abnormal matters contained in such urine. (3) The urine of infective disease is far more toxic than that of other common maladies; this appears to be due to the amount of leucomaines found in such urines.—*Ex.*

# ABSTRACTS.

## RUBIDIUM IODIDE IN SKIN DISEASE.

Dr. Leo Leistikow, of Hamburg, who at the suggestion of Unna, made trials with rubidium iodide at his clinic, reports (*Monat. f. prac. Dermat.* Vol. xvii, No. 10) as follows:

In all cases a five per cent. aqueous solution of rubidium iodide was used, three tablespoonfuls of which were given daily.

Case 1:—Mrs. S., aged 45 years, suffers from two specific ulcers of the hard palate. The ulcers were first cauterized with a ten per cent. solution of chromic acid for three days. After this rubidium iodide was administered internally. Under this treatment the ulcers healed completely in two weeks.

Case 2:—Mr. M., aged 30 years, has a gumma which is located in the *sulcus retroglandularis*. Restoration takes place by external application of a gutta-percha plaster mull containing mercury and carbolic acid, and with a 3 weeks' internal treatment of rubidium iodide.

Case 3:—Mrs. A. I., aged 55 years, is affected with an extensive ulcerating syphilide of the right lower thigh, accompanied by varices of the veins. The treatment consists of bandaging the leg with zinc oxide-ichthyolglue, and prescribing rubidium iodide internally. Restoration results within 14 days.

Case 4:—Mrs. A. H., aged 40 years, suffers from gummatous periostitis of the frontal bone, and besides presents an insufficiency of the bicuspid valve. Rubidium iodide effects a cure within two weeks without influencing the action of the heart.

Case 5:—Mr. R., aged 20 years, shows the first general symptoms of secondary lues; besides specific angina and universal papulous syphilides, extremely violent headaches prevailed. An eight days' inunction-treatment makes the secondary eruptions disappear, but without relieving the headache. Internal treatment with rubidium iodide in double doses for three days caused the headache to disappear entirely.

Case 6:—Mr. M., aged 30 years, who is suffering from secondary syphilis, had just undergone an inunction-treatment and desires to take iodine. He is given rubidium iodide for two days, but owing to violent conjunctival catarrh, this remedy had to be discontinued.

Case 7:—Mr. J., aged 41 years, is afflicted with acute polyarthritis of gonorrhoic origin. By a two weeks' treatment with rubidium iodide he is entirely cured. Appearance of a iododerma pustulosum.

Case 8:—Mr. M., aged 60 years, presents a gumma of the tongue. At first potassium iodide is administered and effects considerable shrinkage, but after eight days produces a violent catarrh of the upper respiratory tract. Potassium iodide is therefore discontinued and substituted by rubidium iodide. This change of treatment causes the symptoms of catarrh to diminish, and after four weeks' use of the rubidium iodide the gumma is healed.

It is especially important to note, that in the one case of syphilis complicated with valvular disease, the heart's action was not in the least influenced by the rubidium iodide. Altogether the rubidium salts have no toxic effect upon the heart like the potassium salts. It is advisable, therefore, to employ rubidium iodide in all cases where the use of potassium iodide is contra-indicated on account of its dangerous effect upon the heart. The symptoms of iodism (the iododerma and the catarrh of the mucous membranes) are not excluded by the use of rubidium iodide. On the other hand, whenever iodism follows the use of Iodide Potassium, these unpleasant accompanying effects may be avoided by the employment of rubidium iodide. Gastric disturbances were never observed. The taste of the rubidium salt is not as disagreeable as that of potassium iodide.

---

PROFESSOR GARNER has returned from Africa and declares that he has learned, beyond doubt, that there is a monkey language, and it can be learned by man.—*Pub. Opinion.*

## CONTRIBUTORY NEGLIGENCE OF PATIENT AS DEFENSE TO CHARGE OF MALPRACTICE.

One of the most interesting decisions rendered for some time in a malpractice case, is that of the Appellate Court of Indiana in Young v. Mason (decided November 22, 1893, and just reported, 35 Northeastern Reporter 521). In this case the jury returned a general verdict for $1,000 in favor of the party claiming injury, and also returned answers to forty interrogatories submitted on behalf of the physician sued. Now answers to interrogatories override a general verdict when both cannot stand together, but not where they can be reconciled.

It was clearly shown by the answers in this case that the physician possessed fair and ordinary knowledge and skill, also that the manner in which he dressed and treated the injuries of this patient was, with one exception, such as is approved and followed by the most skilful surgeons in that vicinity, and which is approved by the standard authors and text writers upon the subject of surgery. The exception was that the answers did not conclusively show that he exercised due skill and care in reducing a fracture near the wrist joint. This act, with other acts of alleged negligence, it was charged caused a certain stiffness of joints and a loss of the use of the arm, for which damages were sought. But the answers also showed that the patient took her injured arm out of the sling, contrary to directions, and placed it on her lap, window sill and table, and that she also refused to allow the physician to use passive motions at the times, and to the proper extent.

Indulging every reasonable presumption and intendment in favor of the general verdict, and granting that the party who brought the action established to the satisfaction of the jury every fact put in issue, except when the answers to the interrogatories affirmatively and conclusively shown to the contrary, and giving a fair and reasonable construction to the facts, which were clearly, specifically, and without conflict or contradiction found in the answers, the court concludes that the negligence of the physician in failing to reduce the fracture near the wrist, and the refusal of his patient to allow him to subject the injured joints, at the proper times, to passive motion, concurring in producing the injuries for which recovery was sought.

The authority of other courts is quoted to the effect that "the law has no scales to determine in such cases whose wrong doing weighed most in the compound that occasioned the mischief." "It is the duty of the patient to submit to the treatment prescribed, and to follow the directions given, provided they be such as a physician of ordinary skill would adopt or sanction . . . A person cannot recover from another for consequences attributable in part to his own wrong."

The law on this very important subject is further illustrated and summed up, by the Appellate Court, as follows: Suppose a man fractures the bones in his leg below the knee, and calls a surgeon to treat the injuries, and the surgeon negligently fails to properly reduce one of the fractures, but in all other respects gives proper treatment, and the patient, in disobedience of the directions of the surgeon, negligently removes the bandages used as a part of the proper treatment by the surgeon, or is otherwise guilty of contributory negligence, and such combined negligence of the surgeon and patient unite in producing a shortness and stiffness of the leg, for which injuries an action is brought against the surgeon, can the patient recover? The patient is certainly not responsible in such case for the original negligence of the surgeon in failing to properly reduce the fracture, but this negligence of the surgeon unites with the subsequent contributory negligence of the patient in causing the shortness and stiffness of the leg. Now it seems clear, under such circumstances, and the authorities cited, that the patient can not recover for the consequent shortness and stiffness of the leg.

Where both the surgeon and patient are free from negligence, or where the surgeon is free from fault and the patient is guilty of negligence, no recovery can be had against the surgeon in any case. It is only where the surgeon is guilty of negligence and the patient is without negligence on his part contributing in any degree to such injuries that the patient can recover damages of the surgeon,—*Jour. Amer. Med. Ass.*

# SOCIETY REPORTS.

## THE LOUISVILLE CLINICAL SOCIETY.

*Meeting, November 7, 1893.*

### ALOPECIA AREATA.

DR. I. N. BLOOM: No. 1—This patient, a young man about twenty years of age, as you will see is suffering from alopecia areata. The feature of greatest interest in the case is the extent of the disease. I think it is safe to say that at least one-half of the hair is gone. He is a young man of exemplary habits, no suspicion even of specific trouble. He has been under my treatment for only a short time, but there is already considerable improvement. I believe in about four to eight weeks the hair will cease to fall out and the new pigmented hairs will appear. Lanugo hairs can be seen in spots, and here and there on the older patches pigmented hairs show up.

I have a lady under treatment at the present time where the disease is about one-half as great in extent as in the case before us.

### EXTENSIVE CASE OF PSORIASIS.

No. 2—This is a plain case of psoriasis, the most extensive, I think, that I have ever seen in private practice. The surface of the entire body is affected, the spots varying from the smallest patch to the size of your two palms. It is because of the unusual extent rather than the unusual disease that I exhibit the patient. He has been under my treatment about a week, and this is the second attack in which I have seen him. The first attack was about two years ago. The treatment has been simply tar; I have also given him iodide of potassium, following out the line of treatment of Chopp and Kotzen, who claim to have gotten good results from large doses of iodide potassium in these cases. He takes thirty-five drops, containing 30 grains of iodide, at a dose three times daily. As a local application I have used 10 to 20 per cent. ointment of oleum rusci. Arsenic is recommended, but this is the slowest method of treatment; it would require about twenty weeks in a case like this. Under iodide of potassium and tar I believe a cure can be effected in six to ten weeks. The extent of surface affected in this case makes me chary of using chrysasobin. Investigations embracing several hundred cases prove that iodide of potassium has absolutely no ill effect on the blood; that it does not increase or diminish the red blood corpuscles. In this connection I wish to say that I have administered in a case of brain syphilis what I believe to be the largest dose of iodide of potassium ever given in Louisville—540 grains daily. All symptoms disappeared in six weeks.

### DISCUSSION.

DR. A. M. VANCE: I remember a case of alopecia I saw when a student where there was absolutely no hair upon the head. It was in the clinic of Dr. Lunsford Yandell at the University. The patient was a boy ten years of age, whose head was as clean as a billiard ball, except the very fine hair that Dr. Bloom speaks of which could be seen only upon the closest inspection. I remember the treatment, particularly how successful it was—at each sitting an area of probably about two inches square was painted with pure carbolic acid and before over one-half of the extent of the scalp had been gone over, the hair began to grow upon the portion that had been first painted. The ultimate result in this case was perfect. The effect when the hair commenced to grow was very noticeable, as it was black.

DR. W. O. ROBERTS: The case of alopecia shown by Dr. Bloom recalls one which a number of the members of this society have seen. His scalp looks very much like the case before us. The patient has been under the care of many doctors, myself included, and among other things used in the case has been carbolic acid, but I could see no benefit from anything that was done for him. I lost sight of the patient for a number of years and a few days ago met him on the street; his head looks now about the same as it did the last time I saw him.

The other case shown by Dr. Bloom is of great interest to me; it is the most beautifully marked case that I ever saw. The patient has post-cervical enlargements, and this leads me to ask Dr. Bloom if he has ever had syphilis.

DR. A. M. VANCE: The so-called psoriasis due to syphilis is not often as extensive as this. I would like to ask Dr. Bloom if he simply takes the history of the case, or are there other ways of differentiation.

DR. I. N. BLOOM: You do not need any history at all in these cases. As this patient appears to-night it is scarcely a fair case: He has been under treatment for a week and the appearance of the spots has changed very materially. Had you seen the patient a week ago when he applied to me for treatment, with the characteristic silvery scales all over his body, you would have made diagnosis of psoriasis without any possible difficulty. As I have already stated two years ago I cured this patient of a similar attack of psoriasis, at that time the spots were only about one-fifth as abundant as now, varying in size from your thumb nail to a silver dollar. There is no syphilitic psoriasis that resembles any other psoriasis, except the so-called psoriasis palmaris syphilitica. In making the diagnosis between the three palm dis-

eases, syphilis, psoriasis and eczema, it is sometimes very difficult and you may have to take the history into consideration. But, generally speaking, a close examination of the eruption on the body will generally suffice. In the previous attack which the patient had, he was treated locally with chrysasobin and the effect was all that could be desired. At that time he received nothing internally.

DR. T. P. SATTERWHITE: Is there any eruption on the hands of the patient?

DR. I. N. BLOOM: No, nor is there any on his feet.

DR. T. P. SATTERWHITE: Is it not a fact that attacks of this character are almost always considered the result of syphilitic involvment?

DR. I. N. BLOOM: No, sir, never.

DR. T. P. SATTERWHITE: Is there any connection between this trouble and gout?

DR. I. N. BLOOM: No, sir.

DR. A. M. VANCE: What is the supposed etiology?

DR. I. N. BLOOM: It is not known. All we know about it is that in the vast majority of cases it occurs before or about the time of puberty. That at times heredity seems to play a part. I am accustomed to say to my patients that I can cure them of the eruption in from four to eight weeks, depending upon the extent of the disease but it may return in six weeks, six months or six years, or never. I have patients who have not had a return of the trouble for thirteen years; in others it has returned in a year; some in six months; in the case reported it has been two years, I prepared him for this, however; my prognosis is very conservative in all such cases. It is a very common disease, but is rarely found as wide in extent as this case shows.

---

MALIGNANT DISEASE OF THE RECTUM.

DR. W. O. ROBERTS: I had a patient come here to-night with view of showing him before the society, but the gentleman whom I wished especially to see the case is not present, therefore I will not introduce the patient. I believe it to be a case of malignant disease of the rectum. I wanted to show it because of the fact that it is the third case that has come under my observation in which the disease is not advanced too far for operative interference. All of the other cases which have come under my observation have gone too far for any operation to be considered. The rule is if the cancerous growth extends higher up than you can reach with the finger, it is beyond all operation looking toward a cure of the disease. This trouble is located in the lower end of the rectum and confined to the posterior wall; an ulcerated surface which does not seem to cover a space larger than a nickel. Above and to either side of the ulcerated surface two nodules can be plainly felt. The man complains of pain in defecation and for a short time afterward, and passes mucous, pus and blood, as he describes it, with each stool. I saw him for the first time to-day; I feel satisfied that it is an epithelioma and a very favorable one for removal.

I recall to mind now a case of cancer of the rectum in a lady whom I saw soon after the trouble began. This is one of the cases where I thought operation would be followed by good results. Dr. Mathews also saw the case in consultation and concurred in my diagnosis. This patient was operated upon in St. Louis, some ten years ago and she seems to be in perfect health now.

---

DR. L. S. MCMURTRY: I have here a group of specimens which I have selected from a series of abdominal sections done within the last few weeks which may be of interest.

HYDROSALPINX.

No. 1.—This is a tumor of the broad ligament, an accumulation of serum in the Fallopian tube. It was very difficult to remove without rupture on account of adhesions. The Fallopian tube you will see is distended with serum, and the ovary is in the broad ligament and not incorporated with the cyst. The fimbriated extremity of the tube you will observe is sealed upon one end of the cyst, and the other end is included in the ligature placed there. It is a hydro-salpinx. The specimen is interesting in its relations to sterility.

TUBO-OVARIAN DISEASE OF LONG STANDING.

No. 2.—Here are two specimens from the same patient of tubo-ovarian disease of long standing. The patient had suffered repeated attacks of peritonitis, and had been an invalid for several years. The ovary and Fallopian tube are so amalgamated as to appear as one mass. On cutting into this mass, after removal, a cavity containing a dark soft material is found, which would doubtless have advanced to abscess.

CYSTIC OVARY.

No. 3.—This is another specimen of tubo-ovarian disease. The operation was done yesterday morning and the specimen is quite fresh. It is a case of cystic ovary with adhesions and involvement of the adjacent Fallopian tube. The disease was bilateral, and illustrates a very severe lesion which is comparatively rare in pelvic inflammatory disease. The cyst contained a dirty, bloody fluid, consisting of decomposed blood and serum. These blood cysts are among the most dangerous of this class of tumors, and are associated with extensive inflammatory lesions. The adhesions were universal.

SUPPURATING DERMOID CYST OF OVARY WITH TWISTED PEDICLE.

No. 4.—This specimen is a very typical il-

lustration of dermoid cyst of the ovary. For some time preceding the operation the patient suffered intensely with active inflammatory symptoms, as you will see the cyst was suppurating. You will observe that the pedicle was twice twisted and is very small. The tumor was very generally attached by adhesions to the intestine and parietal peritoneum. On opening the tumor it is found to contain sebaceous matter, hair, and other material characteristic of these tumors. The surface of the sac is very dark, the result of low vitality from interference with the circulation through the pedicle in consequence of the twisting. These tumors require the utmost care in their removal, as the foul contents of the tumor must be carefully prevented from obtaining contact with the peritoneum.

FIBROID TUMOR OF THE UTERUS.

No. 5.—This is a specimen of fibroid tumor of the uterus. I have had the patient under observation at times for several years. Four years ago it was very small and was producing considerable hemorrhage. At that time I opened the abdomen and removed the uterine appendages, hoping to obtain the same good result from this operation that I have witnessed in a large number of similar cases. The patient was much improved for a time, but the tumor steadily grew and inflicted upon her much pain and distress. She was a frail woman, and in consequence of pain and hemorrhage her health was much impaired. Nervous and other complications came on in time and she was sent from home by her family physician for general treatment, with the hope of improving her general health and relieving the nervous disturbances which were of most serious character. I had not seen the patient to examine her for over two years when I was asked to see her two weeks ago, and found the tumor to have reached these extensive proportions.

Her physician had for some time advocated an operation for entire removal of the growth, and the patient was anxious for anything which promised relief. Her health had failed rapidly of late months, and her sufferings were intense. Several severe attacks of peritonitis during the past year had added to her distress. Her complexion was very bad, her general nutrition impaired, and her sufferings had made her dependent upon daily doses of morphia. The operation was the most difficult of the kind that I have ever undertaken. The tumor was firmly packed and fixed by organized adhesions to every portion of the pelvis. I had literally to dissect it out. The bladder was dissected off of the tumor in front, the rectum was released behind, the utmost care was required to protect the ureters; and the difficulties were increased by a cystic degeneration and suppuration of one portion of the tumor. The operation was completed very satisfactorily at last, and the patient was put to bed in very fair condition considering her extremely feeble condition. On examining the specimen the suppurating portion will be observed. Members of the Society will recall a number of large tumors of this kind that I have presented here from time to time, several of them much larger than this one, but in comparison their removal was easy. The patient never fully reacted from the operation and succumbed two days later.

In all the other cases here illustrated recovery was easy and prompt. Indeed in no one of them did any untoward symptoms arise.

DISCUSSION.

DR. W. H. WATHEN: I wish to say a word concerning two of the specimens exhibited by Dr. McMurtry: The specimen exhibited as a hydro-salpinx is a typical small parovarian cyst. The tube is pervious and healthy, and the cyst is below it.

The dermoid cyst is a pretty specimen of one of the varieties of dermoid conditions that are often met with in practice. No one can tell positively that a tumor is dermoid until it is removed and the specimen examined. I have removed dermoid tumors looking exactly like an ordinary ovarian cystoma, but upon critical examination discovered only a bunch of hair to demonstrate the dermoid origin.

DR. W. O. ROBERTS: In regard to the hydrosalpinx: Several weeks ago I operated upon a young girl fifteen years of age for radical cure of an irreducible inguinal hernia, left side. Upon opening the sac I found the ovary with a hydrosalpinx. As the ovary was found to be in an unhealthy condition, I removed it, together with the tube. The tumor had existed ever since the patient was quite a young child and she wore a truss strange to say, but always had to take the truss off during menstruation, and her sufferings were so intense during that time that she had to go to bed for at least two days. She has menstruated once since the operation with scarcely any pain at all, and her recovery has been uneventful.

DR. T. P. SATTERWHITE: With reference to the fibroid tumor, I want to report one case showing the tenacity of life and one of the complications of operations for the removal of growths of this character. Some years ago I assisted Dr. McCoy of Jeffersonville, Ind., in removing some fibroids from the uterus of a patient; the largest one was about the size of an orange, with three or four smaller ones. I was asked to see the patient again in the course of a month, and the abdomen was enormously distended, inflammation had set up; upon reopening the abdomen we drew off it seemed to me a gallon of pus—the abdomen was divided by adhe-

sions and the pus had accumulated above. Notwithstanding this, the patient lived over a month and then died. I do not remember how many days she lived after the inflammation and formation of pus. The operation was laparotomy.

---

Dr. Cheatham read a paper on

CHRONIC RETRO-BULBAR NEURITIS.

(See page 90 in last week's issue.)

DISCUSSION

DR. T. C. EVANS: Tobacco and alcoholic amblyopia afford a striking instance in which the clinician anticipates the work of the pathologist. Von Graffe in 1866 and Leber in 1869 called attention to the pallor of the temporal half of the optic disc; this in conjunction with the central section led them to conjecture that the amblyopia was the result of a retro-bulbar neuritis. This opinion was confirmed pathologically by Samelsohn and others in 1880 and 1882. They found the pathological condition to be an interstitial sclerosing inflammation—in many respects similar to hepatic cirrhosis. The process involves the pappillo-macular group of fibers and may occur at any point from the nerve head to the chiasm. A few years ago Dr. Uthoff, of Berlin, examined ophthalmoscopically one thousand inebriates in the various asylums—he found the white sector of the disc in 14 per cent. of the cases, a much larger proportion than had hitherto been supposed. I think it not unlikely that similar sclerosis occur in other parts of the nervous system. Most of the cases occurs in those addicted to both alcohol and tobacco. In those using only tobacco the smokers are the ones usually affected.

A case recently came under my observation where the man did not smoke and did not chew excessively, yet he seemed to have a typical case of tobacco amblyopia. His vision when he came to me was reduced to 20 cc.—I advised him to leave off tobacco entirely and put him on strychnia and phosphorus; in a few months his vision came up to 20 xx.

---

DISPLACEMENT OF SEMI-LUNAR CARTILAGE BY INJURY—REMOVAL—RECOVERY.

DR. A. M. VANCE: A young man, a footballist, consulted me some time ago with the history that about a year ago while playing football and making a "stand," I believe they call it, sustained an injury to his knee, "put his knee out of joint," as he called it. He said that it was pulled back and he went on with the game. A number of times he had the same accident, and every time applied the same remedy. Three or four months before he consulted me he began to suffer with pain of a boring character over the head of the fibula, with tumefaction. A week after I first saw him the pain and swelling had increased, and I then thought I could detect an abscess of the cold variety, and incised it. I found the contents to be not only fluid, but considerable caseous material also came out. The cavity of the abscess was thoroughly irrigated, but the pain continued and there was not the improvement I had hoped for. I then increased the size of the incision and removed what I took to be a floating cartilage from the knee joint. Entire recovery soon took place. I feel sure that the body removed was the semi-lunar cartilage.

---

DISPLACEMENT OF SEMI-LUNAR CARTILAGE BY INJURY—REPLACEMENT BY PRESSURE.

DR. W. O. ROBERTS: Several weeks ago I saw a young man who had his knee injured in a game of football. He claimed that a man in the process of the game had struck him on the inner side of the leg between the knee and the ankle, and at the same time another one hit him on the outer side of the thigh, twisting his leg out at the knee-joint. He says it was replaced and he was taken home; while on the way there it was again knocked out and again replaced. I saw him twenty-four hours after receipt of the injury and the knee was enormously swollen, but as well as I could make out the bones seemed to be in perfect position. The leg was put up in plaster dressing which was not disturbed for ten days; when the plaster was removed the swelling had disappeared, and on the outer side of the joint there was quite a protuberance which I thought at first was the result of lateral displacement of the knee, but upon careful examination and measurement became satisfied that it was not, but that it was one of the semi-lunar cartilages displaced. Under chloroform by extension of the leg, and pressure upon the protruded cartilage much to my surprise it slipped in. I feel satisfied in this case that it was one of the semi-lunar cartilages. The plaster dressing is still on, and I am a little inclined to believe there will possibly be a recurrence of the trouble upon the slightest twisting of the knee.

IODIDE POTASSIUM IN CEREBRAL SYPHILIS.

DR. I. N. BLOOM: I had supposed that a a few months ago in speaking of the use of iodide of potassium in cerebral syphilis, I had given the largest dose ever administered in Louisville—540 grains per day. It seems that Dr. Roberts has given a larger amount, and I would like to have him tell us something about the case.

DR. W. O. ROBERTS: The case has already been reported. It was a case of brain syphilis which I saw with Dr. Bodine. Iodide of potassium was administered in gradually increasing doses until the patient received one-half ounce three times per day, a total of 720 grains daily.

# CURRENT LITERATURE REVIEWED.

IN CHARGE OF ELLISTON J. MORRIS, M. D.

THE AMERICAN JOURNAL OF OBSTETRICS for January contains a paper by Dr. Howard A. Kelly on

**The Direct Examination of the Female Bladder with Elevated Pelvis—The Catheterization of the Ureters under Direct Inspection, with and without Elevation of the Pelvis.**

After reviewing the results obtained by others in this field, the author describes his own method by which, he states, any gynecologist, after a little practice, should be able in almost every case to catheterize either ureter within a few seconds after the introduction of the speculum. The following list of instruments and accessories is given by the author as required for the examination: female catheter; a series of urethral dilators; a series of specula with obturators; common head mirror and lamp, Argand burner or electric light; long, delicate mouse-toothed forceps; suction apparatus for completely emptying the bladder; ureteral searcher; ureteral catheter without a handle; several bran bags or an inclined plane for elevating the pelvis. A valuable aid for the beginner searching for the ureteral orifice is the following: A point is marked on the cystoscope five and a half centimetres from the vesical end, and from this point two diverging lines are drawn toward the handle with an angle of sixty degrees between them. The speculum is introduced up to the point of the V, and turned to the right or left until one side of the V is in a line with the axis of the body; then by elevating the endoscope until it touches the floor of the bladder the ureteral orifice will usually be found within the area covered by the orifice of the speculum. The ureteral orifice can often be found by an adept at once, and almost instinctively, by a single movement of the speculum after its introduction into the bladder. The author states that an anesthetic is not necessary for cystoscopy or catheterization of the ureters, unless the urethra is to be dilated up to No. 14, 15, or 16. In nervous women it is often best to make a thorough examination first under anesthesia. Subsequently a satisfactory illumination of the bladder can be made and the ureters catheterized and any ordinary treatment applied through the number ten speculum without anesthesia. A pledget of cotton saturated with a five per cent. cocaine solution, inserted into the urethra seven minutes beforehand, greatly facilitates the dilatation and is often the best form of anesthesia. The author believes it is the duty of the surgeon to examine at once all bladder affections which are more than trifling, to disclose at the exact nature and extent of the disease. The procedure is also of use in defining the ureters in hysterectomy for carcinoma and in some hysteromyomectomies. The paper is illustrated by cuts of the instruments and photographs showing the method of applying them. The article is an amplification of a former paper by the author entitled "My Recent Ureteral Work," published in *The Annals of Gynæcology and Pædiatry* for May, 1893, and reviewed in the issue of THE MEDICAL AND SURGICAL REPORTER for May 27, 1893.

Dr. Philander A. Harris contributes a paper on

**A Method of Performing Rapid Manual Dilatation of the Os Uteri, and its Advantages in the Treatment of Placenta Previa.**

The author believes that the employment of rapid manual dilatation must be restricted to cases of advanced pregnancy where, for any reason, it is desired to effect prompt delivery. Its use presupposes the possibility of the full introduction of the index finger to its largest diameter without much delay or difficulty. If with the patient anesthetized, the index finger cannot in a very few minutes be fully introduced, he would seriously doubt the possibility of successful employment of this or any other manual method of dilatation, and would advise the operator, for the time at least, to cease further attempt. The author's experience with his particular method is limited to seven cases of placenta previa, six cases of crossed birth, and two of eclampsia. The method advised by the author is as follows: The index finger is introduced up to its largest diameter with the os. If the forefinger be now withdrawn till only the tip engages, it will generally be found that the tip of the thumb may be introduced alongside the finger. When the tips of both index finger and thumb are thus within the ring, and the second finger sharply flexed, with the os resting on its palmar and outer aspect, we have but to keep the index and second fingers close together to form a notch from which the os-uterine ring cannot easily escape. This the author terms the first position. The straightened and extended thumb, resting on the outer lateral side of the index finger, is now carried as far from the tip of the index finger as the enlargement of the os will permit. Considerable power for dilatation may indeed be exerted by continuing this movement of the thumb, but a far greater and far less fatiguing force may be exerted if we implant and immovably hold the thumb on the index finger whilst forcibly and together flexing the index and second fingers. When a little headway has thus been gained, we slightly extend the index and second fingers, which will permit the thumb to travel further from the tip of the index finger, at which point we again press and hold the extended thumb firmly against the outer side of the index finger. In this position the holding point is again taken, whilst tonic flexion of the index and second fingers continues the work of dilatation. After a while the fingers are again slightly extended, which will permit the

thumb to be carried still further toward the metacarpo-phalangeal articulation. Whilst holding it firmly on the index finger, flexion of the index and second fingers should be renewed. If tonic flexion of the fingers has been steadily maintained, we shall now be able to introduce the index and second fingers and thumb. The relation of the extended thumb to the first finger is maintained as before, while the os, encircling the thumb and also the two fingers, rests on the dorsal surface of the more sharply flexed third finger, in the same manner as it rested on the second finger before. The power for stretching is derived from fixation of the thumb on the first finger while counter-pressure is effected by flexing the index, second, and the third fingers. In a short time we shall have dilated sufficiently to permit the introduction of the third finger. The os, still hooked over the tip of the extended thumb, will now have its point of counter-pressure between the third finger and the inner latero-dorsal aspect of the fourth finger. Tonic flexion of all the fingers is again resorted to, and the gain taken up by occasional slight extension of the fingers and movement of the extended thumb toward the metacarpo-phalangeal articulation. Gradually, in this manner, the thumb and all four fingers are introduced. Here again the enlargement is effected by flexion of all the fingers, although the index and second will be flexed far less than the third and fourth fingers. This, the author terms, the fourth position, and states that the limit of dilatation in this position for a hand measuring seven and three-quarter inches over the metacarpo-phalangeal articulation (as measured for gloves) is eight and a half inches (circumferential measurement). The extreme limit of possible and easy dilatation with the hand in this position will not exceed the glove measurement more than one inch, which is scarcely sufficient for the easy introduction of the whole hand. He then resorts to what he terms the fifth position, in which the os is made to encircle the first row of phalangeal bones of the fingers, and the second or last phalanx of the thumb. The movement required in this posision is extension of all the fingers, the tips of the fingers being at the same time flexed to lessen their encroachment on the intra-uterine space. A less fatiguing and somewhat more powerful dilating manipulation (which the author terms the sixth position is effected by causing the os to encircle the second row of phalangeal bones of the fingers and the first phalanx of the thumb. In either of the last two positions the degree of circumferential dilatation possible will exceed the above glove measurement by at least three inches. This, of course, is a much higher enlargement than is required for the introduction of the hand into the uterus. The author states that there is neither call for dragging down, or pushing upward of the os; it is dilated *in situ*, while the encroachment on the intra-uterine space is reduced to a minimum by flexure of the tips of the fingers in all the stages of every position. Any normal hand, he thinks, should endure the fatigue consequent on the accomplishment of rapid dilatation, if dilatation is possible. Having once failed to accomplish rapid dilatation, owing to the impossibility of introducing the first finger, the author reminds his readers that it may not be possible to effect dilatation by this method. Appended to the paper is the report of cases in which the author made use of his method. The paper is illustrated by cuts showing the position of the fingers throughout the steps of the manœuvre.

Dr. X. O. Werder reports a case of

**Pregnancy Following a Partial Suprapubic Hysterectomy Complicated by Hemorrhage Through the Abdominal Cicatrix.**

Previous to operation the patient had been subjected to the application of electricity after Apostoli's method for two months, fifteen applications in all, varying from one hundred to one hundred and fifty milamperes. This treatment neither affected the size of the tumor nor did it produce the slightest symptomatic improvement, so that the patient clamored for operation. The tumor was attached by a very broad and thick pedicle to the posterior and right surface of the fundus of the uterus. The base of the tumor was encircled by an elastic ligature, above which the pedicle needles were passed, and the tumor removed above this point. The uterine cavity had not been opened, though subsequent events proved that part of the uterine tissue had been included in the ligature. The pedicle was fixed in the lower angle of the wound in the usual way. Pedicle and ligature came away onthe twentieth day and the patient left the hospital about six weeks after the operation with a small fistulous opening at the bottom of the abdominal wound. She missed the second period after the operation and developed symptoms of pregnancy. At the end of the fourth month there was a copious hemorrhage from the fistulous opening, which by this time had become enlarged from internal pressure to the size of a half-dollar, the amount of blood lost being at least a pint according to the estimation of the patient. There were seven hemorrhages in all, five of which were profuse, producing marked anæmia of the patient and causing a great deal of anxiety as to the ultimate result. Labor began three weeks before the expected time and the first stage was very slow. Labor was terminated by forceps. During labor there was only a slight oozing from the fistulous opening. The child was living but was very small and thin. The placenta was found adherent just under the fistulous opening and required manual separation. At this place the hand in the uterus noted an apparent absence of the uterine wall, and the placenta seemed to be attached to the abdominal wall around the external sinus. The abdominal wall was extremely thin, as could easily be ascertained by the hand placed over it and pressing against that in the uterus. Patient made an uninterrupted recovery. The reporter states that there is no doubt in his mind that the slough under the elastic ligature extended into the body of

the uterus and on separating opened into the uterine cavity; and that there was a direct communication between the fistulous opening in the abdominal wound and the uterine cavity, which allowed some of the menstrual blood to escape through it at her menstrual period; and that, furthermore, the source of the hemorrhages during pregnancy was the placenta itself, the upper edge of which was attached immediately under the bleeding surface.

The principal points in the case described are:

1. The menstural discharge through a small fistulous opening remaining after a partial supravaginal hysterectomy, which communicated with the cavity of the uterus.

2. Pregnancy occuring eight or nine weeks after operation in a woman previously sterile, in spite of a utero-abdominal fistula.

3. Pregnancy terminating in the delivery of a healthy though poorly developed child, at or at least near, the end of her term, in spite of a firm and unyielding fixation of the uterus to the abdominal wall, and in spite of frequent and profuse hemorrhages, from the placental site, through a sinus opening in the lower angle of the abdominal cicatrix.

Dr. H. Meek reports

**A Case of Tubal Pregnancy With Some Peculiarities.**

The peculiarities consisted in:

1. Situation above and in front of the uterus, between it and the pubes, the usual situation being behind the uterus.

2. The uterus being retroverted behind mass and on the same side instead of being displaced to the opposite side.

3. The intermittent contractions, which were so like contractions of the pregnant uterus as to lead one to think it a case of pregnancy in one horn of a double-horned uterus.

After examining the literature at his disposal, the reporter comes to the conclusion that the situation of the tube sac, above, in front, with the uterus back and on the same side, is unique.

No flushing or drainage was used at the operation. The patient made an uninterrupted recovery.

Dr. A. Brothers discusses

**The Present Position of the Electrical Treatment of Extra-uterine Pregnancy.**

The author finds that twenty-five cases which he has been able to trace were doing well after a lapse of one to eight years, and that none of them had been compelled to undergo secondary operations. Many of these patients still carry traces of the old trouble, but without perceptible inconvenience. The author analyses the literature on the subject, presenting a table of cases treated by electricity. He finds that only one death—that of Janvrin's patient—has occurred in seventy-eight cases in which electricity was employed without puncture, and in this case there were marked symptoms of hemorrhage previous to the resort to electricity. Of the seven cases treated by electro-puncture, there were five recoveries and two deaths. This proves that electro-puncture is a very dangerous method. The bad results being undoubtedly due the puncture and not to the current.

Dr. W. S. Christopher, presents

**A Plea For the Study of Pediatrics.**

It is the author's opinion that every reputable medical school should appoint a full professor of pediatrics. This professor should include in his lectures and clinics not only a discussion of the diseases of children, but, so far as time will permit, he should impress upon his class the wide scope of the subject and elicit an interest in its development. He should use his influence with the faculty to establish in the school a study of the fundamental branches upon which his own is dependent. Thus in anatomy he should secure the dissection of infants and the study of embryology in a properly equipped laboratory. In physiology and chemistry he should secure the laboratory work on the chemistry of food stuffs, the processes of digestion, assimilation, and elimination. In pathology the morbid anatomy and bacteriology of early life should receive formal attention.

Dr. Andrew F. Currier contributes an article on "Myoma Uteri and Its Treatment." [An abstract of this paper appeared in *The Annals of Gynæcology and Pædiatry* for November, 1893, and was reviewed in the issue of THE MEDICAL AND SURGICAL REPORTER for December 2, 1893.—ED].

The remaining papers in this issue are: The report of "The First Symphysiotomy in America," by Dr. Wm. Thomas Coggin; the continuation of the paper by Dr. Anna M. Galbraith on "Poliomyelitis Anterior Acute Infantilis;" and a paper by Dr. Flanklin H. Martin on "Ligation of the Broad Ligaments of the Uterus for Uterine Fibroids," with the report of the author's sixth case. The operation was a complete success.

---

THE MASSACHUSETTS MEDICAL JOURNAL

for January contains a paper by Dr. D. J. Kelley on

**Tubercular Meningitis,**

reporting a case. The patient was a little girl of nine years, the child of healthy parents. The first symptoms were noticed about three weeks before the doctor's first visit and consisted of nothing more than a gradually increasing hebetude and sleepiness accompanied by a slight headache at the vertex. No impression was made on the patient by any treatment and she gradually sank, toward the last refusing all food. The temperature was taken daily; there was no increase until twenty-six hours before death when it rose to 99½°. The pulse although very weak, was always regular and never more than 90, until the last two days, when its frequency rose to 140 shortly before death, which occurred quietly, without the least struggle, ten days after the doctor's first visit. There was no paralysis or paresis; no convulsions; no papillary or visional disturbances at any time; nothing but a constantly increasing headache and sleepiness from the beginning of the attack to the dissolution of

the patient. The following is the report of the post mortem:

Removing the calvaria no adhesions were noticed between the dura mater and the bone. The dura mater itself was very tense, and slight adhesions along the longitudinal fissure could be readily observed between it and arachnoid. The tubercular character was at once manifested on the removal of the dura mater. The tubercular granulations were moderately sprinkled on the whole convexity of the brain, especially along the sylvian fissures. And where the tubercles were most abundant a very slight amount of lymph could be seen. Removing the brain and examining the base the same was noticed; the tubercles, however, existing in greater abundance, and lymph had been thrown out in greater quantity, especially over the central portion of the base, the optic commissure, and the pons. The vascularity of the brain was well marked. The ventricles were filled with a large amount of clear serum and the tubercles were largely disposed over the choroid plexus.

Dr. E. A. Lewis discusses

**Rigidity of the Os Uteri,**

reporting a case. The patient was twenty-nine years old, plethoric habit, and in her first confinement. The doctor first saw her after she had been sixteen hours in labor. He found that the waters had been escaping gradually since the first hour of labor; pains frequent and very lancinating. Having waited three hours, and finding the os not inclined to dilate, the author prescribed an opiate, and directed the vagina to be syringed with a tepid antiseptic solution. Two hours later there had been no improvement. Three one-grain doses of opium were given at intervals of an hour without effect. Extract of belladonna was also applied to the os without result. After the woman had been eighteen hours in labor the author decided to resort to operative measures. By careful manipulation the index and middle fingers were introduced within the os, and it was thus expanded to the extent of two inches in diameter. Owing to the exhausted condition of the woman, the author decided to terminate the labor at this point by the use of the forceps. A living nine-pound child was delivered, the mother made a good recovery. The author advises the employment of the above treatment in cases of rigidity of the os. The author speaks of an experience of seven cases in which he practiced the method and delivered five living children; all the mothers made a good recovery. He advocates the early resort to the forceps in such cases. When rigidity is confined to the os and neck, caused by some former organic disease of these parts, the treatment must necessarily be somewhat different. Should there be any hardened cicatrix of the os, the result of former ulceration or inflammation, incision of the cervix may be necessary.

Dr. Frederick Wallace Abbott contributes a paper on

**The Antipyretic Value of Hot Water used Externally.**

Its use is especially recommended in those cases of enteric fever characterized by a cool surface, feeble cutaneous circulation, and marked depression, where the thermometer will disclose a very high temperature showing a determination of blood to the great vessels and internal organs. The class of cases in which hot water may be profitably employed, the method of its application, and the auxiliary measures to be adopted, must be determined at the bedside. Broadly speaking, however, the young, the old, the debilitated, and those of a nervous temperament, are most benefited by the hot-water treatment, although its use is by no means restricted to these. As to the method of using hot water, this must be adapted to individual needs, the facilities at hand, and, as most of us sadly realize, the notions of the family and neighbors. In the treatment of meningitis, the exanthemata, and other febrile conditions in the young, we put the little patients into a warm bath, and gradually add hot water till the desired temperature is reached. A sense of comfort will be immediately experienced, and the patient may fall into a quiet slumber while in the bath. The bath should not last over fifteen minutes, when he should be gently rubbed dry, wrapped in a blanket, and returned to bed. If cardiac weakness exist, a little stimulant may be administered just before the bath; and, though held to be contraindicated in cases of fatty heart and atheroma of the great vessels, the author has yet to see any ill attend this treatment. The process may be repeated several times during the day, the guide to its frequency being the benefit derived. If it be deemed inadvisable to employ the hot bath, much good may be had from frequently sponging the entire surface, and hot cloths profitably be applied to the head, spine, and chest. Many who shrink from the application of cold water, and are even injured by it, will derive much satisfaction and benefit from hot sponging, and request its frequent repetition; and an antipyretic agent of no mean value is offered, the author believes in this treatment.

The remaining paper in this issue is by Dr. R. E. Anderson, entitled "Medicine as Practiced by the Lower Animals." In it the author points out the remedies selected by the sick animal, such as the various grasses.

---

### Lysol in Obstetric Practice.

Israelson (*St. Petersburg med. Woch.*, No. 47, 1893) urges the use in obstetric practice of lysol as having greater antiseptic properties and a less poisonous action than any coal-tar derivative hitherto known. He uses a 1 per cent. solution for the skin, etc., and a 2 per cent solution for instruments, this preparation being less milky than the former. No pains, but only slight burning sensations are produced by the use of either, and it has no irritant action on the skin. Owing to lysol forming a "lather" with water it is a substitute for soap, rendering unnecessary the inunction of the hands and the application of soap and water prior to operations. The author has tried lysol extensively during one year and a half with satisfactory results.

# PERISCOPE.

IN CHARGE OF WILLIAM H. BRICKER, M. D., B. SC.

## MEDICINE.

### Catrin on Observations upon Mumps.

The author has made a careful analysis of 159 cases and concludes as follows:

1. Mumps being indifferently upon either side: generally the parotid swelling begins as unilateral, affecting the other side after a lapse of from several hours up to five days.

2. Prodermic symptoms are the rule. In sixty-two out of a hundred cases there is at the same time an inflammation of the pharynx.

3. In twenty-four cases out of a hundred there is an initial fever, ordinary slight, but it may rise to 40°C., and last four days.

4. The prognosis as to complications is not determined either by the degree of severity of the glandular swelling or the intensity of the pain.

5. In half the cases the submaxillary glands participate in the process.

6. The duration of the treatment should be at least fifteen or twenty-five days.

7. The disease attacks especially young men serving in the army.

8. It is evidently contagious, but the germ is easily resisted, and prolonged exposure is necessary to infection.

9 The period of incubation appears to be about fifteen or twenty days. Relapses are more common than generally believed as they occur in about 6 per cent. of cases.

10. A distinction must be made between the true orchitis of mumps and the simply testicular injection which is never followed by alteration in gland structure.

11. Among other complications may be cited rheumatism, otitis, localized œdema, endocarditis, albuminuria, and purulent orthritis.—*L'Union Medicale.*

### Harley (Vaughn) on Diabetic Coma.

After recounting his experiments in the porduction of artificial coma in dogs by the introduction of sugar into the circulation, Harley describes the coma as: 1. A stage of nervous irritation, which may be so severe as to assume the form of an epileptic convulsion, or so mild as to appear in the form of mere trembling of the skin. 2. A comatose stage which may merely amount to a few hours' drowsiness or extend to a deep coma from which the animal cannot be roused, and ending in death.

The cause of the preliminary nerve irritability stage is probably due to the formation of some as yet undetermined substances acting as an irritant to the nerve-centres, the comatose stage being in its turn due to the effects of various toxic substances combining to produce it. The coma seems to be principally due to a diminution in the alkalinity of the blood produced by the acid products derived from the breaking up of the sugar molecule, the acids combining with the sodium carbonate and bicarbonate as well as with the ammonia in the blood, and thus hindering the blood carrying the carbonic acid to the lungs for elimination; while there is at the same time a diminution in the oxygen absorbed, and thus the oxidation in the organism is hindred from being properly carried on by a process of tissue asphyxia.

The artificial coma produced in the writer's experiments, while it is exactly analagous to that occurring in diabetic patients, does not appear to depend upon an increase in the quantity of the sugar in the organism, but upon the increase that has taken place in its derivatives. In all probability the same products are being continually formed in the health body, but only in such small quantities and so gradually that they are either sufficiently rapidly eliminated or there is sufficient time for them to be further transformed, in the process of metabolism, into harmless substances, and consequently are never present in the blood in an amount capable of producing coma.

In the cases of diabetes due to diminished assimilation of the sugar in the organism, such as pancreatic diabetes, coma occurs when the sugar has disappeared from the urine. From some cause as yet undiscovered the normal power of breaking down the sugar molecule in the ordinary processes of metabolism has been regained, and since the quantity of sugar present both in the tissues and the blood had been previously increased, an excess of its products is produced, and hence the coma. This point is of practical importance, as it indicates that one ought always to be on the outlook for coma, whenever a diabetic patient's urine ceases to contain sugar, if its disappearance cannot be accounted for either by dietic or other treatment. By analyzing the urine and finding acetone, or aceto-acetic acid, as well as making quantitative estimation of the ammonia and the lactic acid in it, one may be able not only to predict the outset of coma, but prevent it.

The rational treatment founded on the results obtained from the experiments is to administer alkalies. If the symptoms are urgent and time is of moment, sodium carbonate might be administered subcutaneously or intravenously, the pulse being carefully watched in case of heart failure. At the same time, since there is so great a diminution in the oxygen absorbed, it is advisable to encourage oxidation. The inhalation of pure oxygen may help, as well as trying to improve oxidation by massage. Diuretics together with large quantities of fluid hasten the elimination of the toxic products derived from the sugar.—*Brit. Med. Jour.*

### On the Restriction and Prevention of Tuberculosis.

The committee appointed by the American Public Health Association, in conjunction with the International Congress of Public Health, has published the following report:

1. Tuberculosis has been conclusively demonstrated to be contagious, by bacteriological experiments, by clinical observations, and by a study of the history of the disease.

2. Tuberculosis is a preventable disease. Its preventability follows as a logical sequence upon its contagiousness, but has likewise been demonstrated in a practical life.

3. The contagium of tuberculosis resides entirely and solely in broken-down tubercular tissue. A person suffering from tuberculosis, therefore, does not become a source of danger to others until he begins to give off broken-down tubercular tissue, either in the form of sputa from the throat or lungs, diarrœal discharges from the bowels, or matter from a tuberculous sore, such as lupus, white swelling, cold, abscess, scrofula, or tubercular inflammation of a joint.

4. A person suffering from tuberculosis can be made entirely harmless to those about him by thorough sterilization of all broken-down tissue, immediately upon its being given off. With proper precautions it is, therefore, possible to live in the closest relationship, and upon the most intimate terms, with consumptives, without contracting the disease.

5. Tuberculosis is not hereditary. A predisposition to the disease can be transmitted from parent to offspring, but this is more true of tuberculosis than it is of all other contagious diseases.

6. A predisposition to tuberculosis can be created anew by malnutrition, or by anything which depresses the nervous system.

7. Tuberculosis affects animals as well as man, and is identically the same disease in both. In domestic life human beings and animals mutually infect each other.

8. The media through which human beings are ordinarily infected by animals are milk and meat.

9. Houses in which consumptives have lived, and in which immediate sterilization of all broken-down tissue has not been practised, are infected houses, and are liable to convey the disease to subsequent occupants.

10. Spitting upon floors and into handkerchiefs, and permitting the broken-down tissue to dry and become pulverized, is a prolific cause of spreading tuberculosis.

11. Temporary occupation of hotel rooms, sleeping car berths, and steamer cabins by consumptives in the infectious state, can infect them so as to convey the disease to subsequent occupants, unless proper precautions are taken against contamination of the bedding, furniture and walls with booken-down tubercular tissue.

We recommend the following practical measures for the prevention of the disease:

1. The notification and registration by health authorities of all cases of tuberculosis which have arrived at the infectious stage.

2. The thorough disinfection of all houses in which tuberculosis has occurred, and the recording of such action in an open record.

3. The establishment of special hospitals for the prevention of tuberculosis.

4. The organization of societies for the prevention of tuberculosis.

5. Government inspection of dairies and slaughter houses, and the extermination of tuberculosis among dairy cattle.

6. Appropriate legislation against spitting into places where the sputum is liable to infect others, and against the sale or donation of objects which have been in use by consumptives, unless they have been thoroughly disinfected.

7. Compulsory disinfectants of hotel rooms, sleeping car berths, and steamer cabins which have been occupied by consumptives, before other persons are allowed to occupy them.—*N. Y. Med. Record.*

**Koster (H.) on the Treatment of Erysipelas.**

During the past year Koster has treated about fifty cases of erysipelas with local application of white vaseline. A moderately thick layer of vaseline is applied with a brush over the affected area and over the surrounding healthy skin. Over this is laid a piece of ordinary linen, or, in case the face is affected, a linen mask with openings for eyes, nose, and mouth. The dressing is held in place by a gauze bandage. Fresh vaseline is applied twice daily and the same saturated mask is again laid over it and bound down. The results were exceedingly favorable, being quite as good as those obtained by painting with iodine, ichthyol, or corrosive sublimate-lanoline. In most cases the fever fell by crisis in a few days, usually two or three; pain and tension diminished rapidly, and relapses were not more frequent than under other treatment. The success of the treatment was sometimes surprising. The area of inflammation did not increase in most cases. Good results were obtained on the scalp without removing the hair. The method of treatment is recommended by its simplicity and freedom from dangerous or irritating properties.—*Centralblatt f. Klin. Med.*

---

**Hysterical Œdema.**

W. Gajkevicz (*Gaz. lekarska*, No. 39, 1893) reports the following case: A girl, aged 18, previously quite healthy, suddenly noticed a swelling of her right upper extremity, but, as no pain or redness or rise of temperature was present, she paid no attention to it. After three weeks, pain of a localized character set in the swollen extremity; the right leg also became painful, and after a short time the patient lost her voice. She was well nourished, and the organs of circulation and respiration, and the kidneys were normal. The right arm was 2 to 4 centimetres thicker than the left; not painful; no "pitting" on pressure, pale, with a temperature of 33°C. (as against 35°C on the left), and greatly increased secretion of sweat. Pricking with a needle did not cause bleeding in the right arm, but was followed by a rather obstinate urticaria. During the seven months she stayed in the hospital the right breast and right leg down to the knee also became œdematous. The absence of any disease of the heart and kidneys, and the presence of nervous disturbance, determined the diagnosis of "hysterical œdema."

## GYNECOLOGY.

### Wyhe (W. Gill) on Dysmenorrhœa and Chronic Endometritis.

Undue importance has been attached to retroversion, and other displacements as the direct cause of symptoms. Displacements simply complicate disease, and may give rise to pain, which, however, is due less to the displacement than to other conditions.

When the broad ligaments are thickened, and the tubes and ovaries diseased, pain will be experienced, as the subject assumes the upright position, even when there is no displacement from the downward pressure exerted upon the fixed uterus and diseased ovaries. When the uterus is healthy, displacement causes but little trouble.

If retroversion exist, next determine whether the case be complicated by disease of the endometrium, or by salpingitis.

If disease of the tubes and ovaries be present, the only procedure is their removal. We cannot treat disease of the Fallopian tubes by curetting and draining. We cannot reach the seat of disease except by laparotomy.

If no such complication exist, boro-glyceride tampons should be placed twice a week between the menstrual periods—but pessaries have no place in treatment.

If such treament fail to effect involution and improved circulation, and the introduction of the sound cause bleeding, or pain, then douche, curette, and drain, making a simple application—never one that will destroy the mucous lining with its deep seated glands and follicles, leaving a scar that will do more harm than good in after life.

As to the curetting, the sharp instrument only is worthy of use. The blunt copper wire currette may turn up the granulations, but will not remove them, leaving behind a better nidus for sepsis than before the dilatation. When there are large pieces of tissue to be removed, blunt and rounded forceps are to be used.—*Internat Jour. of Surg.*

## OBSTETRICS.

### Zabala (L.) on Resuscitation of the New-Born.

The instrument suggested consist of two parts, the catheter and the ball. The catheter is metallic and curved in one half whose end fits to the shape of the infant's glottis, with one hole on the outside for the passage of the air. The curve of the catheter is regulated by the convexity of the floor of the mouth. The exterior end is straight and adapted to one opening of the elastic ball. This ball is made of soft rubber, and has two openings, one with a metallic aperture, to receive the outer end of the catheter, and the exterior to allow the entrance of the air. Its capacity is calculated to answer to the inspiratory capacity of a new-born's lungs, thus avoiding the risk of their over-distending.

The infant in Sylvester's position, or better still, in a pail of hot water, as in De Forest's. After cleaning the fauces with my fingers wrapped in a cloth, I enter the mouth again with my bare left index pressing the tongue till I feel the epiglottis; I go as far as filling the cavity of the glottis with the point of the finger. Once there, I hold my catheter and carry it to the larynx, when I push the end straight into its cavity. I keep it in place with my left hand, while with my right I fix the empty ball to the outside and I next produce a movement of aspiration that answers very well for the purpose of emptying the new-born's trachea and bronchi of all foreign substances that may have lodged there. I clean, then, the ball and apply it empty again until I believe that the respiratory passages are totally free, and not until then do I force the air into the lungs. The movement of the insufflator ought to be made at the rate of from fifteen to twenty times to the minute and continued with hope of success as long as the beatings of the heart are not totally extinct.—*Loth. Cal. Practitioner.*

## ARMY AND NAVY.

U. S. ARMY, FROM DECEMBER 31, 1893, TO JANUARY 20, 1894.

The extension of leave of absence granted Captain Charles E. Woodruff, Assistant Surgeon U. S. Army, is further extended one month and twelve days.

Leave of absence for two months, on Surgeon's certificate of disability, with permission to leave the Department of Dakota, is granted First Lieutenant Charles F. Kieffer, Assistant Surgeon U. S. Army.

Leave of absence for one month, on Surgeon's certificate of disability, is hereby granted to Major Edward B. Mosely, Surgeon U. S. Army.

## NEWS AND MISCELLANY.

The Medical Society of the State of New York will hold its eighty-eighth annual meeting February 6, 7, and 8, in the City Hall, at Albany.

Communications relating to the presentation and reading of papers should be addressed to the business committee *prior to the 1st day of February.* Dr. Henry Flood, Elmira, N. Y.; Dr. L. Bolton Bangs, 31 East 44th St., New York City; Dr. Edward Clark, 271 Franklin St., Buffalo, N. Y.

The faculty of the Medico-Chirurgical College, of Philadelphia, has erected three new clinical chairs, viz: Genito-urinary surgery, orthopedic surgery and otology. These together with the vacancy in the chair of clinical medicine will be filled permanently at the end of the present session.

### CINCHONA IN MALARIAL AFFECTIONS.

R. G. SAYLE, M. D., Hale's Corners, Wis.

In 1638, the Spanish Viceroy's lady, Princess De Chinchon, was sick with a fever at Lima, and a decoction from the bark of a native tree was administered and the patient cured. The tree was named after this noted patient, and ever since that date cinchona preparations have been held in high esteem in the treatment of all fevers, and especially have the virtues of this drug been demonstrated in the cure of malarial fever. Indeed, the action of the agent is so well understood, and its administration so effective of good results in the hands of the average practitioner, that I feel timid in presenting a paper on this subject.

However, in view of its great importance as a curative agent, placed second only to morphia in our Materia Medica, and in view of the extensive experimentations and studies of later years as to the *modus operandi* by which quinine cures malaria, the best preparations to use, proper dose, best mode of and form for administration, time to administer and value and use of the drug as a prophylactic in malarial diseases, that I offer the following brief outline of cinchona in malarial affections as my convictions resulting from reading the opinions of noted writers and investigators on the subject, coupled with quite an extensive experience of my own with the agent in the treatment of these diseases during the past three years.

We have in cinchona preparations a positive remedy for the active manifestations of malaria. I do not mean by this to include every ailment with periodical phases of expression, but those diseases the result of the entrance into and development and multiplication within the circulation of the malarial organism termed *Plasmodium malariæ*. The periodic processes in an individual affected with malaria are no doubt dependent upon certain phases in the development of these particular low forms of animal life. Quinine being absorbed and entering the circulation meets with these organisms and exercises a restricting power over their development. If the dose administered has been sufficient, the next expected paroxysms will be averted; if not, the remaining active organisms pass on to the reproductive stage and another paroxysm occurs proportionate in severity to the lack of efficiency of the first dose given. The recurring expressions of renewed activity at remote periods are most likely due to development from latent parasites which were located outside the circulation where the effect of quinine was not felt.

*Mode of Administration.*—Having diagnosed our case, we have three practical methods by which to introduce the remedy, viz., the stomach, rectum and hypodermically. Administration by the stomach will offer the least obstacles in the vast majority of cases, the rectum being resorted to in case great nausea or vomiting is present, or the patient cannot or will not take the medicine otherwise.

The hypodermic syringe may be used in

case of a pernicious attack, or whenever profound malarial poisoning is present, and more certain and rapid action is required. Favorable sites for injecting are the buttocks, between the tuberosity of ischium and great trochanter, over the lumbar region and in upper arm. These sites are less sensitive, and in case of a possible abscess resulting, the points of least inconvenience.

*Preparation to use.*—Of the many cinchona preparations the salts of the alkaloid quinine possess every advantage to be derived. For stomach administration the sulphate of quinine answers well all requirements, unless it be in the case of children, when the question of palatableness may influence the physician to choose the tannate. For rectal administration the sulphate answers all purposes. For use in the hypodermic syringe solubility is desirable, and the hydrochlorate has become most popular, though the sulphate is deemed as worthy by many. Quite recently two French physicians and chemists, Drs. Laborde and Grimaux, have brought forward a new salt of quinine, viz., the chlorosulphate, possessing the same action as the ordinary sulphate in similar doses, but soluble in its own weight of water, and said to give rise to much less pain when administered hypodermically than is caused by any other quinine salt.

*The size of the Dose.*—Ten to fifteen grains per day of the sulphate will break up the paroxysm of an ordinary case of malaria, and more than forty grains are seldom needed for the worst cases. It has been determined that five grains of quinine sulphate in the blood of an ordinary individual gives a proportion, the strength of which will destroy the reproductive powers of malarial organisms. Quinine is very readily absorbed by the rectum when retained, and the dose need be but little larger than that taken by the stomach. Five to fifteen grains of the hydrochlorate may be given hypodermically. Quinine tannate possesses about one-fourth less alkaloid than the sulphate.

*Time of Administration.* — The best time to administer quinine is in the decline of the febrile stage or in the sweating stage of the intermittent form of the disease. A full dose should be given at this time, from fifteen to twenty grains, and if another paroxysm fails to occur, the dose need not be repeated, but if a rise of temperature occurs again, give a smaller dose as the temperature wave declines. I am a firm believer in the temperature wave as indicating the time to administer quinine rather than the occurrence of chills, as I have met many cases where, though chill failed to recur, the temperature nevertheless rose to from 103° to 105° F. There is no need of repeating the dose of quinine when neither chill nor rise of temperature recurs, but serious mistakes will often be made if the dose be omitted because the patient reports "no chill to-day." When disagreeable symptoms ensue from the administration of ordinary sized doses of quinine, three, or four, or five grain doses should be given at intervals of two hours, or even smaller doses less frequently, proceeding cautiously until cinchonism is produced. It is a common practice to give a full dose of quinine at intervals of seven days for three or four weeks following the last paroxysm, for the purpose of preventing the expected renewed activity of latent organisms, and perhaps there are not many objections to this practice where quinine is well borne; but in other cases a careful watch is kept over the reappearance of slight symptoms, whether nervous, pertaining to the digestive tract, or otherwise, which usually mark each individual case, and then dose the case if a slight temperature rise is shown by the thermometer. I have not observed this return of the paroxysms in the great majority of my cases. These recurring remote paroxysms are less apt to be experienced where treatment is begun before the system is very much impressed with the disease.

*Form of the Dose.*—With the advent of wafers and the gelatine capsule much of the objection of taking this drug was banished. We do meet those who cannot swallow a capsule or wafer, and object to having their skins pierced or rectum disturbed, so that there is a call for some way other than these for preparing the dose. By many the bitterness is tolerated when given in any form of solution; and I have found that a full dose of quinine placed on the tongue, the mouth closed and a flow of saliva excited, with which the powder is incorporated and swallowed, gives very little bitter taste—the concentrated dose is such that the sense of taste is paralyzed. If the tongue

be first moistened with licorice, a dose of quinine may be given in plain water without any great ojection. Many children of four years and over will swallow a capsule if rightly guided in their efforts. My plan is to first give a teaspoonful of water to moisten the mouth, then give the capsule with directions to roll it about in the mouth (making no mention that they are to swallow it) until it becomes slippery. When the patient says it is in such a state give a glass of water from which to take a good swallow or two, and the pill usually disappears. Members of the family or others, looking on, admonishing "Johnny" to "swallow it!" and "don't bite it!" etc., will usually frustrate the success of this plan. It is easy for a child to swallow a capsule unconsciously and just as readily he can prevent the act, if his attention is directed in particular to the dose. The tannate of quinine is a very eligible preparation for children. It may be extemporaneously prepared as follows: Quiniæ, twenty-four grains; acid tannic, twelve grains, mix with two ounces of syrup of cinnamon, or, if the sulphate be used, double the quantity of tannic acid. For hypodermic injection, quinine hydrochlorate, twenty grains; acid hydrochloric, five drops, and water distilled fifteen minims, may be compounded, fifteen minims corresponding to about seven and one-half grains of neutral muriate of quinine. Quinine sulphate mixed with a little water, and dilute sulphuric acid added drop by drop until the salt is dissolved, and enough more water added to make the desired quantity, answers well.

The new salt chloro-sulphate may be dissolved in an equal weight of water. For intravenous injection, quinine hydrochlorate fifteen grains, sodium chloride eleven and one-half grains, add water distilled, two and one-half fluid ounces, mix, boil and filter the solution before using. For rectal administration dissolve ten to thirty grains of sulphate of quinine in dilute sulphuric acid, add a few drops of laudanum, and make the quantity two to four ounces by the addition of wator, and inject through a rectal tube well up in the bowel.

*Idiosyncrasies and Contra-indications.*--Most of these may be overcome by judicious administration as to time and dose. Unpleasant brain symptoms are improved by giving a full dose of bromide of potassium or hydrobromic acid. My own experience with the drug in pregnant women has convinced me that no contra-indication to its use exists. In middle ear affections quinine should be given in small doses. There are many minor expressions of idiosyncrasy toward quinine which must be tolerated in view of the known benefit to be gained.

*Quinine in the Prevention of Malarial Infection.*—There will be no development of malarial organisms in the blood when a sufficient amount of quinine is in the circulation, consequently ten grains of quinine sulphate may be taken daily on coming into an infected locality, especially if one must needs be exposed at night or occupy lower rooms for sleeping apartments, or live on low ground. If these disadvantages are not present, or proper hygienic surroundings can be secured, continued use of quinine may be omitted.

---

THE TONGUE IN "LA GRIPPE."—"La grippe" is a disease which, simulating as it does various other pathological conditions, is often puzzling from a diagnostic point of view. Who, on being called to cases of "la grippe," has not thought of such possibilities as typhoid fever, acute tuberculosis, cholera, simple "embarras gastrique," etc. If one may believe M. Faisans (*Societe Medicale des Hopitaux*, May 19) examination of the tongue will disperse all such doubts. The tongue in "la grippe" is of the normal size and form, not being broad and thick, as in "embarras gastrique," or small, contracted and pointed, as in typhoid fever. It is always moist, unless some inflammatory complication be present or imminent; it is smooth and even, papillæ not being prominent. But the chief characteristic feature of the tongue is its color, it is the *opaline tongue*. The opaline coloration is sometimes uniformly spread over the whole lingual surface; in other instances the middle and the base are opaline, the edges and tips being covered with distinct rounded opaline or bright red spots. This pathognomonic appearance may be often noted from the first onset of the disease and may persist for a more or less prolonged period after recovery. Purgatives and emetics do not modify it in any degree.—*Lancet* correspondence. *Maryland Medical Journal.*

# LITTLE HELPS AND LITTLE HINTS CONCERNING THE PROPER FEEDING OF INFANTS.

JAMES ALLEN PATTERSON, M. D., SALEM, N. J.

No doubt every practitioner has been frequently impressed with the increasing inability of mothers to suckle their offspring, and the difficulty of obtaining a proper substitute for nature's provision. It therefore behooves us to study deeply and observe minutely, that we may meet the various demands made upon us, and surmount obstacles as they arise.

I have oftimes noticed the inability of the laity to appreciate the fact, that infants require feeding in proportion to their digestive ability and constitutional requirements. Many mothers labor under the erroneous impression that because an acquaintance feeds her babe in a particular manner, her own child, which may be of the same age but of entirely different diathesis and digestive capacity, can subsist or thrive upon a like regimen. There are more infants starved in cell-growth than many are aware of. While some may manage to make out a fretful and diseased existence in babyhood and suffer through life from the ills due to a depraved constitution, many perish by the wayside an easy prey to some epidemic which may attack them.

I am firmly of the belief that a child, particularly if fed upon an artificial food, should be constantly watched, and when it is found that sufficient gain in body weight is not being made monthly, that its flesh is pale, flabby or in any wise of unhealthy appearance, that it is not sleeping well or is fretful, its diet should be varied or radically changed and any constitutional dyscrasia prescribed for. It is my experience that a child who digests well and is properly nourished, sleeps well and is happy and good humored, at the same time making continuous gains in size and weight while maintaining a healthy complexion and elastic flesh. Children that are fretful and sleepless are as a rule fed in a faulty manner or upon food which they cannot fully digest.

As a substitute for breast milk, we naturally turn to cow's milk, from the comparative ease with which it can be obtained and the experience which every one knows of its ordinary adaptability. But cow's milk has disadvantages, which have been frequently pointed out, namely: its excess of curd and its acid reaction.

The excess of curd is somewhat counterbalanced by dilution, and its acid reaction by alkalies, but in subtracting the excess of curd by dilution we lower the amount of fats and albuminoids, thereby losing elements of food value.

The dried preparations of milk and starchy ingredients, sold as various infants' food have rightly been tabooed by eminent and experienced clinicians.

Years ago, Charles D. Meigs, saw the advantages derived from cream and milk, to which was added a starchy ingredient. The food compound bearing his name, consists of cream, milk, arow-root, gelatine and sugar. While not an ideal compound, having the disadvantage of containing starchy ingredients in a form not easy of assimilation, the gelatine being of questionable food value and the cane sugar too prone to ferment, it did a good work in its day.

Various cream mixtures have been proposed and used since the time of the elder Meigs. The leading ones being those of his son, A. V. Meigs, of Biedert, and of Rotch.

The above three compounds while being very similar in composition are almost identical in analysis to that of breast milk, and agree with some infants. They have the disadvantage of being troublesome to prepare and keep, in addition to containing sugar of milk, an article which is liable to contain gritty particles, which do not always dissolve promptly; an article which is quickly "converted into lactic acid, so that the excess of acid accumulates in the stomach and causes the protein substances to coagulate and become indigestible; it dissolves the alaklies and calcium out of the phosphatic combinations to no purpose except to produce dyspepsia and diarrhœa and, according to Heitzmann, rhachitis," (p. 49. Jacoby Intestinal. Diseases of Children). In addition "many specimens of milk-sugar have been found to contain bacteria derived from the milk from which it is made."

(Neuman *Berl. Klin. Woch.*, 1893, No. 22, quoted in *Am. Med.-Surg. Bull.*, December, 1893) the low temperature habitually used to separate it from the milk not being sufficient to kill them.

Rotch, whose formulæ is—

℞
Cream (twenty per cent).....3iss
Milk.....3i
Water.....3v
Milk Sugar.....3iij¼
Lime Water.....3ss

makes a very strong point in his mixture by advising the use of centrifugal cream, the ordinary strength of which is twenty per cent. This manner of separating the cream from the milk by machines making 7000 to 9000 revolutions per minute, cannot fail to produce a more minute subdivision of the globules than is obtainable in the old manner of skimming, or the somewhat similar plan of drawing the milk from the cream by gravity. Centrifugal motion has in addition a cleansing action upon the product, as after the machines have been in use, their sides are found filled with a filthy ingredient, resembling a tough curd containing pus, blood and filth from various sources. I speak from ocular inspection, having made no microscopical examination of it.

The requirements for an ideal food for infants appear to be dilution to lessen the proportion of curd, the addition of cream to supply the requisite amount of fat and of an assimilable form of starchy ingredient to maintain the separation of the curd in finely divided masses, whilst supplying certain deficient and valuable food values, and an alkali to counteract the acidity of the cow's milk.

The amylaceous ingredient can only be obtained in assimilable form by converting the starchy grains used into the diastasic products dextrin and maltose, while maintaining much of its mechanical effect upon the minute subdivison of the curd.

My plan has been to use cream, or cream and milk with Mellin's Food, a food which consists of the dextrin and maltose products of wheat and barley alkalanized. It supplies the sweetening power and albuminoids in a much more palatable and digestible form, than the cream mixtures above spoken of. I have used both and believe the food compound is more easily digested and has given me better results. And is it to be wondered at when we recall the researches of Musculus and O'Sullivan, who confirm the physiologically important question *that* the action of malt diastase is identical with the action of the salivary and pancreatic secretions, ptyalin and amylopsin. (Digestion and Diet by Sir Wm. Roberts, p. 26). Again the experiments of Schiff have proven that "in many cases of vomiting" dependent upon insufficient formation of pepsin, injections of solution of dextrine will enable the stomach to resume its function, or being injected into the rectum, will furnish an absorption material for the secretion of pepsin." (Infant Diet by Jacobi, p. 96 and 105).

The following formula has given me excellent results:

For a child aged from three to six months, six to seven tablespoons of cream, with or without three of milk, three of Mellin's Food and water one quart, gradually increased to ten of cream, and five each of milk and of Mellin's Food to the quart. I direct that the cream and milk be first scalded with the desired quantity of boiling water, when sufficiently cold the Mellin's Food is to be dissolved in it and the mixture placed in a refrigerator. When the child is to be fed the mixture is stirred and sufficient quantity warmed, in this respect merely following the directions supplied with each bottle of the food.

When the patient's stomach is in a demoralized condition, I begin with the cream and Mellin's Food combination only. When that agrees I gradually add the milk.

A child of two months, suffering from marasmus is doing well upon a formula consisting of five parts of cream, one of Mellin's Food, and five of water. At first it required to be fed by the spoon, being too weak to draw from a nipple, and was only able to take four to six ounces in twenty-four hours. In a week, subsequently, it took a quart in twenty-four hours, while its digestion as shown by the cessation of diarrhœa and absence of colic, heretofore troublesome symptoms, has become normal. Its increase in body weight and growth is surprising.

THERE were treated at the World's Fair Emergency Hospital, 18,500 cases, and there were 23 deaths at the institution.—*Pub. Opinion.*

# FRACTURE OF THE EXTERNAL AUDITORY CANAL BY BLOWS UPON THE LOWER JAW.

ROBERT BARCLAY, A. M., M. D.,† St. Louis.

Fracture of the osseous external auditory canal and its integumentary tissues by force transmitted through the inferior maxilla is not infrequent; and its importance arises from the fact it may be overlooked entirely or, if not so, mistaken for a fracture of the base of the skull or for a ruptured membrana tympani.

The mode of occurrence and the behavior of such cases are sufficient to place the medical attendant upon his guard against oversight or error is diagnosis; and it is with a view to contributing further to the stock of general information respecting this phase of the subject that the following clinical memoranda are displayed.

*80447l.*—This man, aged forty-nine years, first consulted me eight days after having been kicked upon the symphysis of the inferior maxilla by a mule. Following the injury, there had been free hemorrhage from both external auditory meatus for a day, when a moist antiseptic compress was applied to both ears. After several days, there was substituted for this dressing a wad of absorbent cotton-wool plugging the outlet of the meatus. A mephitic discharge, however, supervened, and was active at the time of our first consultation; upon which occasion, after properly cleansing the parts, although slight hemorrhage persisted from the canal wound, the diagnosis of fracture of the anterior-inferior bony canal wall and its coverings was readily made. A similar lesion, but without persistent hemorrhage, was found in the other ear. No lesion of either drum-head could be recognized.

The auditory canal was continuously distended with a tent of absorbent cotton-wool, tightly rolled, conical in form, saturated with an emollient, vulnerary ointment. The injured parts healed rapidly.

*604448.*—Ten days before our consultation, the patient, a man aged thirty-three years, had been kicked by a mule, sustaining thereby three scalp-wounds and a compound fracture of the inferior maxilla upon the right side. No aural injury had been suspected until the day before our consultation, when a discharge from the right meatus was discovered.

After the ear had been carefully cleansed, it was not found difficult to recognize a fracture of the anterior-superior and medio-inferior wall of the bony canal and its coverings. Search was carefully but unsuccessfully made for a suspected lesion of the drum-head.

Treated, as the preceding, with the ointment and cotton-wool tent, the patient, I have been informed, made a rapid recovery from the aural injury.

*604345.*—This man, aged forty-six years, complained that "his ears had felt stopped up for five weeks" preceding; that "his head felt as if it were full of water," and "sometimes as if there were a sticking in it, and as if it would burst." With the worse, the right ear, he could hear loud voice at three feet distance. Hitherto he had received no treatment.

On examination, the cartilage of the concha was, upon both sides, found slightly drooping at the meatus. The left auditory canal was found greatly narrowed by encroachment of the anterior wall, seemingly from diffuse bony growth thereof. The right one had in like manner been reduced to a mere vertical slit, about one-sixteenth inch wide at its broadest part; and it contained impacted cerumen, which was at once removed. There were two carious teeth upon the right side of the upper jaw; which doubtless by reflex irritation had induced the oversecretion of cerumen within the ear connected with them. In a search for the etiology of the deformity of the auditory canals, inquiry elicited the statement that ten years previously he had fallen a distance of thirty feet, sustaining a fracture of the inferior maxilla; and although he

†Formerly Ass't Aural Surgeon to the New York Eye and Ear Infirmary; Member of the American Otological Society; Aural Surgeon to the City Hospital, Henrietta Street Hospital, St. Mary's Infirmary, South-Side Dispensary, St. Louis' Baptist Hospital, Missouri Baptist Sanitarium, Convent of the Good Shepherd, Marise Consilia Deaf and Dumb Institute, St Louis; Consulting Aural Surgeon of the Hospital Department of the Missouri Pacific, St. Louis, Iron Mountain and Southern, and of the Miss uri, Kansas and Texas Railway Companies, etc.

could not recall the condition of his ears nor assert the existence of any auditory symptoms at the time, when suffering intensely from his maxillary fracture, it may reasonably be inferred, from the aural appearances, that the glenoid process may have been fractured at that time.

*604171.*—The patient, a man aged twenty-eight years, while under the influence of liquor, was struck upon the zygomatic process of the temporal bone, and upon the inferior-maxillary joint of the right side. The right ear bled profusely for two days, clotting up with arterial blood. During that time hydrogen peroxide had been instilled into his ear three or four times a day.

Incidentally it was learned that he was quite deaf in the other, uninjured ear, having been so ever since an attack of scarlatina at the age of five years.

Upon the third day, when I first saw him, the clots, etc., were removed from the right ear; when without difficulty the lesion was identified as a fracture of the glenoid process with rupture of the anterior structures of the canal. Under treatment similar to that described above, the patient made a good recovery.

*604035.*—The occasion of injury in this case was unknown, it having occurred while the patient was intoxicated.

Two days after his mishap, I saw him, a man forty-nine years of age, and noted these facts; there were found, at that time, contusions and ecchymosis of the face; lymphangitis of the right fore-arm from trauma of its posterior portion; abrasion of the left auricle at the antihelix; left aural hemorrhage from a laceration of the left auditory canal, fractured by a blow that had produced as well a compound fracture of the inferior maxilla; and the left drum-head has been ruptured.

Under instillation of hydrogen peroxide and distension with the anointed cotton-wool conical wad, the aural injury rapidly healed, and the patient made an uninterrupted recovery.

# COMMUNICATIONS.

## HYSTERECTOMY.

L. S. McMURTRY, M. D., Louisville, Ky.

In connection with the two specimens, which I here present, I will report the cases which I deem of exceptional interest and illustrative of two of the most important classes of cases in pelvic surgery.

The first case is one of cancer of the uterus which I saw about ten days since in consultation with Dr. Krim. The patient had been bleeding for some time, and had suffered severely with reflex nausea and vomiting. A vaginal examination revealed the unmistakable symptoms of malignant disease involving the cervix. There was also a boggy mass within the pelvis to the right of the uterus, which I feared was extension of the disease in the broad ligament, but which proved to be a pyo-salpinx. One week ago yesterday I did vaginal hysterectomy and the operative technique was as follows:

For three days preparatory to the operation, the patient received daily and thorough vaginal douches of a solution of bichloride of mercury. Two days prior to operation I thoroughly curetted the uterus, removing the necrosed tissues. At the time of operation the vagina was again thoroughly douched, and the cervical canal packed with iodoform gauze. These precautions are essential in order to prevent infection of the peritoneum in the course of the operation. Seizing the cervix with forceps, it was drawn well forward and the tissues divided with the scissors posteriorly, opening the peritoneum into Douglas' space. At this stage of the operation a clean sponge, to which a strong ligature was attached, was passed into the peritoneum up above the field of operation so as to prevent descent of the intestines. With the index finger of the left hand as a guide, and after drawing the cervix backward, I divided the tissues anteriorly and dissected the uterus from the bladder, being careful to avoid the ureters. The incision in the vaginal mucous membrane was completed all the way round the cervix, and the uterus brought well down. I then placed a clamp on the left broad ligament near the

uterus and attempted to treat the right broad ligament in the same way. At this period of the operation I discovered the boggy mass, previously mentioned, was a pyo-salpinx on that side. When the clamp was compressed it ruptured, and pus ran down into the vagina. I divided the broad ligament on the left side, and also on the right, when I discovered that the right broad liagment was so disorganized that it would not hold the clamp. I caught up and tied the ovarian and uterine arteries on that side, and removed the diseased tube and ovary. After thoroughly irrigating, and seeing that all bleeding points were controlled, I removed the sponge from within the peritoneum, placed an iodoform gauze drain in the vagina, and around the clamps, so as to secure drainage. The patient was then placed in bed. I removed the clamps at the end of thirty-six hours; there was no hemorrhage. The patient has made an easy and uneventful recovery. She has had no vomiting since the operation, is nourishing well, and already exhibits marked improvement in her general condition.

An examination of the specimen shows that the infiltration has involved the body of the uterus, and that amputation of the cervix after any method would have failed to remove the diseased tissues. This has been the condition demonstrated in greater or less degree of every specimen that I have seen removed, and I am confident that total excision of the uterus is the only treatment worthy of consideration in cases of malignant disease of this organ. The mortality of the operation has been reduced until it is now a very safe proceddure, and the ultimate results would be a great deal better if the cases could be submitted to operation earlier in the course of the disease.

The second case is also one of hysterectomy, but wholly different as to the character of the disease and the method of operation. The disease is a large myoma of the uterus and the operation was done by the supra-pubic route. The superior border of the tumor lay on the inferior curvature of the stomach, and occupied the entire pelvis and the greater portion of the abdomen.

An examination of the specimen shows a peculiar formation of the tumor, which very materially determined the method of dealing with the pedicle. It will be observed that the tumor has a large nodule posteriorly which filled the hollow of the sacrum, and as I open the cavity of the uterus you will observe that the tumor is sub-peritoneal interstitial and sub-mucous, filling up the cavity of the uterus, obliterating the cervix so as to present the form of the gravid uterus at term. The patient is 32 years of age, and has suffered severely from pressure and hemorrhage. She was much reduced in flesh and strength. Since the tumor impinged upon the stomach she has suffered with frequent vomiting. On opening the abdomen, the incision extending from the pubes to sternum, I found difficulties in dealing with the broad ligaments on each side, and the bladder in front. The bladder had been carried upward by the tumor and I had to dissect it off from the anterior surface of the growth. I ligatured the broad ligaments on each side in successive sections, dividing them as tied, until I reached the floor of the pelvis, being careful to secure the ovarian and uterine arteries. Finding the peculiar formation of the tumor which I have described, I finished the operation by complete extirpation of the cervix, and closing the vagina, being careful to suture accurately the peritoneum. I completed the operation with very little loss of blood, and put patient in bed with a pulse of 97, without shock. I put in a glass drainage tube. It is now seven days since the operation and the patient has made one of the smoothest recoveries I have witnessed after abdominal section. I removed the drainage tube at the end of 24 hours and she has done well continuously. The pulse has remained under 100 throughout, and she has suffered no pain, never requiring a single dose of opium or of any anodyne. Indeed she received no medicine whatever except a saline purgative on the third day, and her convalescence has been exceptionally easy and uneventful. I have watched the case with unusual interest, as this is the first one of the series of abdominal hysterectomies which I have done in which I have treated treated the pedicle in this way. In all of my other cases I have treated the pedicle extra-peritoneally with the neude, and have had no reason to regret it. In this case I would have pursued that method but for the peculiar conformation of the

tumor, which necessitated complete excision. This latter point will be appreciated by an examination of the specimen before you.

Until recently professional opinion made very light of fibroid tumors of the uterus. They were pronounced benign, regarded as harmless, and the menopause held up to the patient as a period when cure will come in nature's own way. With increased knowledge of pelvic diseases it was realized that these tumors do not shrink away at the menopause, and that often they grow with increased rapidity after that period. Hemorrhage does not always cease at that period, and degenerative changes, often malignant, take place. Hemorrhage and pressure undermine the system and suffering is severe and protracted. Hypodermatic medication with ergot and local treatment by electricity may palliate, but they never cure. Surgical treatment alone can be relied upon in the treatment of these growths, a fact which is now very generally recognized by the profession.

A large proportion of fibroid tumors of the uterus may be arrested and even cured if treated in the early stages by removal of the uterine appendages. In some cases this operation will fail. It is only applicable to the early stage of these growths and especially in cases where hemorrhage is the conspicuous feature. In some cases where the tumor is of comparatively moderate size, one of the appendages may not be accessible by abdominal section in consequence of the altered relations made by these irregular growths. In many cases where the tumor is sub-peritoneal it may be removed by myomectomy and the integrity of the uterus preserved. This operation is applicable to sub-peritoneal tumors which can be enucleated without opening the uterine cavity.

Hysterectomy is the operation of widest application in the treatment of uterine fibroids. Operators are divided as to the best method of treating the pedicle—one division advocating the extra-peritoneal treatment of the pedicle with the wire *neude*, and the other adopting the intra-peritoneal method. It has been objected that the *neude* is the application of the same principle in this operation as the clamp in ovariotomy, and that it should be abandoned in like manner. It must be remembered, however, that the pedicle here is composed of muscular tissue, very prone to retraction and hemorrhage, and differing in the degree of vitality from the pedicle of an ovarian cyst. The extra-peritoneal method with the *neude* is practiced by Keith, Bantock, Tait and Price—their cases are the most numerous and their results the best. This method is, as a rule, easier of execution and requires shorter time, the latter being a very important factor in avoiding shock. This method requires skill and ingenuity in securing a pedicle, reducing it to small size, so that it can occupy small space in the lower angle of the incision and be divided by the wire without a wet slough. This method is an absolute guarantee against hemorrhage, since the pedicle is under the eye and hand of the surgeon and nurse.

The dropped pedicle is the method of Schrœder, and has been modified since his day. By some it is treated with several rows of sutures, and by others the cervix is completely enucleated. Results have undoubtedly improved recently by all methods, and each operator will doubtless do best with that method in which he has perfected himself and become familiar with details of managing the pedicle. In selecting between the two great methods of dealing with the pedicle it is important to bear in mind that hemorrhage is a great danger after this operation, and whatever method may be selected, the operation is a difficult one.

The results of hysterectomy for fibroid tumors have improved wonderfully within a few years past, and when the great element of time is more generally appreciated by the profession, the operative treatment will be far more successful. When the tumor is of moderate size and the system not exhausted by hemorrhage and pressure, the operation can be done with better results than in cases where the tumor has risen high up in the abdomen and the patient exhausted by loss of blood.

CONSTANCE.—He spends it in buying the papers to see when they're published.

OGDEN WARDE.

# ELECTRO-PUNCTURE FOR REDUCTION OF TONSILLAR HYPERTROPHY, WITH CASES.

S. G. DABNEY, M. D., Louisville, Ky.

This instrument is one for accomplishing the reduction of tonsillar hypertrophy by means of the electro-puncture. Cases in which it is used are generally adults. There are two reasons for the adoption of this method in preference to other means of removal of the tonsils: First, it lessens the danger of hemorrhage, especially in patients where there is a hemorrhagic diathesis; second, in cases where the tonsil is deeply situated it is quite impossible to catch them in the tonsillotome, and it would be dangerous to attempt removal by the knife or scissors. In the opinion of a great many surgeons in this department, the removal of tonsils in the adult in any case is attended with serious danger of hemorrhage. In regard to the flat, deep-seated concealed tonsils, two or three cases occur to me at the moment which may be of interest:

No. 1—A young lady who spent last winter in Florida in order to try and secure relief from a very persistent cough. She has a family history of phthisis; she has been examined, however, by several physicians in the city who failed to find any evidence of tuberculosis; the sputum has never been examined. The cough recurred again this fall, and there was a sense of general discomfort about the throat. When she consulted me, on my first examination I was almost inclined to believe that there was no condition of the throat which could produce a cough. There was apparently no enlargement of the tonsils, there was little or no hyperesthesia of the parts, and she complained of very little trouble; but on pulling back the anterior palatine fold I found the tonsil was larger than it should be, and upon inserting a probe I found it the seat of the most intensely disagreeable odor, indicative of a septic condition. This patient came to my office two or three times per week for about six weeks, and was entirely relieved of all distressing symptoms and the persistent cough, under the use of the electro-puncture. This rather tedious treatment is really the objection to the electro-cautery; the patient has to be under the doctor's attention for such a prolonged period and make so many visits. The cough was evidently due to the deep-seated trouble in the tonsil, as there appeared to be no pulmonary trouble, and the cough has almost entirely disappeared.

No. 2.—Another case I happen to have just now has tonsils much like the one just reported. The patient has the most decidedly coated and offensive tongue that I have ever seen. He complains of pain and discomfort in the throat, not easily located at any one spot. He has consulted several physicians in this city, and has been treated for his throat by one or two gentlemen without very favorable result. When I began treating him I found he had some post-nasal inflammation, which was treated with the usual applications of carbolic acid, iodine and glycerine, and with cleansing sprays to the nose. On his next visit I detected some deep-seated tonsillar trouble, with intensely offensive, disagreeable odor. I have made very free application with electro-cautery to his tonsils, and when this source of sepsis is removed I believe the tongue will also clear up. Perhaps some of the general physicians present can tell us something about the relations of tonsils of this character to indigestion. Of course the connection between the throat and the stomach is a mutual one, each affecting the other. It is claimed by many authorities that tonsils of this nature are a very frequent cause of digestive troubles. This character of tonsil very often dips far up into the palatine arches, and is sometimes the seat of the disease upon which one of the members of this Society read a paper some time ago—the disease known as mycosis, which often involves the fourth tonsil and base of the tongue also.

In the use of the instrument under discussion, the number of punctures to be made at one time depends upon the extent of the trouble and the toleration on the part of the patient. I puncture two or three times at the first visit. I treat only one tonsil at a time.

As regards medicinal treatment of tonsillar affections like those referred to, I

do not think we accomplish much by local medication of any character. We all know how many medicines have been advocated for the reduction of tonsillar hypertrophy and for the removal of tonsillar inflammation. The saturated solution of chloride of zinc has not been effective in my hands. I have tried several, but so far cannot see that I have gotton any very positive results. Perhaps next to actual removal the application of strong antiseptic solutions, such as bichloride, carbolic acid, and, perhaps, chromic acid, would be most effective.

I think the drift, for the last few years, of specialists in throat diseases, as well as others who do work in this line, has been rather against the use of the tonsillitome in adults. At a recent meeting of the Medico-Chirurgical Society, I reported a case in which I removed the tonsils of a lady, æt 25, where secondary hemorrhage came on five or six hours afterward; not very severe, still enough to show how difficult such hemorrhages might be to control. Of course the complete removal of tonsils in children by use of the tonsillitome or knife, is the proper procedure, as the danger of hemorrhage is very slight; but in the adult, owing to the danger of hemorrhage, especially that of a secondary character, the tendency is toward the electro-puncture.

## NON-OPERATIVE TREATMENT OF SALPINGO-OVARITIS; ITS RESULTS AND LIMITATIONS.*

GEORGE ERETY SHOEMAKER, M. D.†

The value of the so-called conservative treatment of inflammations of the tubes and ovaries is a subject on which there is a wide difference of opinion among medical men; a large part of which difference arises from a misunderstanding of the cases to which it applies, and also from personal prejudice for or against operative treatment in this class of diseases. In the first place it is not always remembered that the highest permanent good of the patient is the object of all treatment; and the old adage, that what is one man's meat is another's poison, applies nowhere better than to cœliotomy in these cases.

The questions constantly presented for solution not only include those of degree of organic change, but the decision as to whether or not operative measures are to be used involves a careful consideration of an infinite number of circumstances in the life of the patient. For example, sterility, to some a curse, to others a blessing, to others a matter of indifference, is a very different question in the young and in the old; to the widow or to the mother of a large and struggling family. Again, a degree of disability, which can be readily borne by a woman of luxurious purse and indefinite opportunity to take care of herself, will ruin the life of one who must work or starve. It is sometimes asserted that the rich have as good a right to be free from pain as the poor. It may be answered that both have an inalienable right to an unmutilated body if this can be secured to them with fair comfort, and that this can be done for the rich in some cases where it cannot be done for the poor. There are important undercurrents, too, in domestic relations which cannot be ignored in the married, or in those who will afterward become so, as every close student of human nature must acknowledge.

It follows then, that in a given number of gynæcological cases, after we have selected the tumors, the major lacerations and the pus cases, aud have advised the knife, the only safe treatment for most of them, there will remain a still larger number who, besides being anæmic and possibly hysterical or hypochondriacal, or who may even be in good health otherwise, will present the condition named in our title, usually with a retroverted uterus, and often with more or less ovarian prolapse. The tubes and ovaries have at some time been inflamed possbily from eposure during menstruation, from an injury, or as a sequel to a general disease. This inflammation did not go on to pus formation, but left serious effects behind it; serious

*Read before the Obstetrical Society of Philadelphia, 1893.

†Visiting Surgeon to Methodist Hospital, Philadelphia.

in their effect on the individual largely because of their persistence and their interference with a life of healthy activity. The patients complain of bearing down, pain in walking, dysmenorrhœa, the pain frequent preceding the flow, while numerous nerve symptoms depend more or less on the duration of the case, the degree of anæmia and the fibre of the individual. These patients have probably received a great deal of treatment, usually not systematically carried out by a specialist, they have been over cautioned not to exert themselves or "do too much," have become introspective and have long ago given up systematic exercise because it caused pain and was supposed to increase the trouble. They have become completely discouraged and often apply, or are sent by physicians, expecting to have their appendages removed.

Two questions must be answered for each case:

First. Will the woman be improved by the operation, and ought it to be done in her case?

Second. What are the prospects, temporary and permanent, of systematic non-operative treatment?

Let it be borne in mind that this discussion does not relate to appendages where no demonstrable disease exists. The question of operation does not arise here. None should be performed. I am in the habit of answering the first question, to begin with, that removal should not be done until other treatment, known to be carefully applied, has failed. Again, I am guided as to prognosis without operation by the amount of organized *adhesions,* and to some extent by the amount of prolapse of ovaries. A considerable experience of patient effort to release them leads to the conclusion that if the appendages are badly adherent and prolapsed, even though all soreness be removed by treatment and the patient be made comfortable, relapses are certain and frequent, and no definite progress toward real cure can be made from year to year. While periods of practical comfort, perhaps months in duration, may be secured by treatment, some exposure, some unwonted strain, as of household care or illness or one of the thousand and one depressing causes of ordinary life will put the patient where she was before. As a result of this experience, in a small proportion of the cases of salpingo-ovaritis which I see, where there is no reason to suspect pus, I counsel removal of the diseased organs. Especially is this done where adhesions are insurmountable, and where there seems to be valid ground for considering the lesions present to be the starting point of stubborn reflexes. In deciding the question as to whether or not adhesions are insurmountable, there is nothing so good as a patient trial by iodine or ichthyol, by boroglyceride tampons, by elastic wool packing and by careful stretching. I would not be misunderstood as meaning that these measures will have any appreciably effect on strong, well-organized adhesions. Such are too resistant to the fingers and too hard to separate after cœliotomy to allow such an opinion. Bowel, bladder, ureter or vein will tear long before some well-organized fibrous bands will give way. The point is that at a first examination, comparatively recent and therefore absorbable adhesions can not always be distinguished from more permanent ones, and under patient efforts to release continued, it may be for weeks or months, many an adherent fundus and adherent ovary or tube can be freed.

As before stated, I would decide to remove an appendage diseased in a lesser degree, if occuring in the mill worker, as compared with the woman of leisure. The struggle for an honest living is hard enough for the healthy; it is hopeless for her, who must lose many days of many weeks and be gradually so unstrung by pain as to lose her capacity for work in nervous invalidism. In other words, it is necessary in deciding these cases to understand fully the life, character, surroundings, work of each individual, and he who possesses the broadest knowledge of humanity will find help from all his knowledge.

Where the lesions are not so gross as to make the decision to operate imperative, there must be weighed against removal, beside the risk to life, which should be very small, the questions of contributing disease in eyes, throat and nose, nervous system or digestive system, conditions which may be practically irremediable. Well weighed, too, must be the possible abolition of sexual desire, with its curious psychical influences; the possibility of hernia in from 5 to 10 per cent. of cases

by old methods, the persistence of adhesions of bowel, bladder or omentum to stump or to cicatrix; the flushings and paræsthesiæ which group themselves about the monthly molimen, even though there be no flow. Though these points vary greatly in importance in different patients, no one who takes the trouble carefully to question patients who have had a section more than a year previously will ignore them. It has fallen to the lot of the writer to follow the fortunes of many who have been operated upon by himself and others, and to operate a second time on some of them. No operator can afford to belittle these points when it comes to the consideration of cases of the comparatively minor character under discussion. Of course, such points are far out-weighed in the presence of major lesions, which have been purposely excluded from consideration here.

## TRANSLATIONS.*

### A CASE OF TETANUS TREATED WITH SERUM.

Dr. Moritz, (*Munch Med. Wochen*, No. 30, 1893.) reports a patient, boy, aged twelve, developed a well-marked attack of tetanus in five to six days, i. e., jaws locked and extremities somewhat stiffened. The patient was admitted to the Polyclinic. The day following admission there was accelerated respiration, weak, compressible pulse, cyanosis, occasional delirium, moderate fever. Method and time of infection not clearly stated. Blood free from tetanus toxin.

On the eight day the patient received the first injection 50 ccm, Hehrings serum, (Heilserums) into each thigh. The pain and sleeplessness was combatted with chloral and morphia, 30 ccm., were given on the next day and 15 ccm., on the day following. Signs of improvement were slow in presenting themselves. Not until the last injection on the fifth day were any noticeable signs present. The head became more movable; the attacks of suffocation less often; the mouth could be opened somewhat; the cramps lessened in frequency and severity. The patient was considered cured between two to three weeks after the treatment had been instituted.

The author believes this desirable result to be entirely due to the use of the serum.

A discussion following the reading of this paper, gives us the opinions of a few others interested in this subject.

*v. Ranke* has used the same treatment in a boy aged 9, having used in divided doses, subcutaneously 60 ccm. of the serum. The boy was cured, and in this case there were no unpleasant symptoms, not even a rise in temperature.

*Buchner* suggested a more careful study of these isolated cases, particularly in relation to the action of the serum, as also, its early use.

The poison present with its attendant symptoms can not be removed by the serum. It is only possible to establish a condition of immunity, thereby preventing any further propagation, thus arresting any further destructive changes.

*v. Ziemssen* reported a case occurring in his practice, moderately grave in character. Bacteriological investigations, however, proved negative; other symptoms present distinctly those of tetanus.

He used 100 ccm. subcutaneously in divided doses, which were followed by decided local reactions. The patient recovered. v. Ziemssen, however, believes the patient would have recovered in spite of the injections.

*Brunner* expressed himself rather skeptically regarding the therapeutic use of the serum. A patient under his care, suffering from a grave attack, died in a short time in spite of its use.

*Moritz*, however, thought the serum had not been carefully prepared, nor had Brunner used it in sufficient quantities.

—W.

*Translated for The Medical and Surgical Reporter by the translators W. A. N. Dorland, M. D., and M. B. Werner, M. D.

## EXTIRPATION OF BRAIN TUMORS AND THEIR RESULTS.

Dr. V. Bramann says: The first case, that of a man, æt. forty-six, had received an injury to the head early in the year 1890. In October, 1891, there was some weakness in the left hand and changes in the muscles of the left half of the face. These were followed by clonic cramps of the left hand, arm and side of face. Consciousness was never impaired. This was followed by a paralysis of the left hand and left portion of the face. The operation was performed in December, after the method of Wagner. The temporary osteoplastic resection of the cranium in the region of the right side of the forehead and ascending frontal convolution was made. In this region a large, smooth cyst was found.

The microscopical examination of the extirpated dura and brain matter showed it to be a myxo-sarcoma with degenerated cysts. An increase of the convulsions produced the necessity for a second operation and was followed later by a third. After this latter the convulsions were cured. The paralysis gradually disappeared, as did also the slight appearance of a choked optic disc. Three months later all the symptoms had disappeared with the exception of a slight paralysis of the left hand and fore-arm.

Case 2. An intracranial brain tumor, weighing 280 g., occupying about two-fifths of that portion of the cerebral hemisphere. The patient recovered.

An artist, aged twenty-nine, suffered up to his eighteenth year from suppurating otitis media. In April, 1891, he had right sided pains in the head, accompanied by dizziness.

These were followed by three attacks, similar to apoplexy, leaving a weakness of the left hand and left half of the face. There was double vision, a marked diminution in sight, loss of memory, choked disc, more in the right than in the left, paresis of the left arm and leg, sensitive points on pressure in the right temporal region, twitching of the left half of the face. Trephining performed in May, exposing the lower half of the central convolutions, showing a tumor simulating a formation of an egg, 8 cm. long and 7 cm. wide. It was easily removed. Five weeks after the operation, consciousness returned, sight improving, and an improvement in the left sided hemi-parseis. The growth was a mixed spindle and round cell sarcoma. The appearance of choked disc and neuro-retinitis optica are constant symptoms where there exists much endo-cranial pressure.

In growths of the cerebellum we find, as a rule, those of the frontal and parietal lobes the most frequent—and those of the temporal region least often. If the tumor is located on one side the eye of the same side will be affected. In tumors of the cerebellum near the tentorium cerebelli, the choked optic disc will occur in both eyes at the same time.

Tumors located near the base of the frontal lobe often produce hemorrhages or ecchymoses of the retina. Occipital tumors near the tentorium cerebelli may give rise to choked disc on both sides; the intensity of the attack however may be unequal. In cases of tumors occurring at or near the temporal lobes, choked disc occurs more rarely (unless in the case of a rapidly growing one, abscess.) In the majority of such cases, it is present in both sides. Circumscribed tumors which displace the brain tissue will give rise to these changes more rapidly than the diffuse (abscess, etc.,) variety; should primary location, however, be near a sinus (sinus transversus) the latter variety will at once give rise to the grave symptoms described. *P. Allertoni* and *A. Brigatti*, also, report a case of a girl aged fifteen, who suffered since her tenth year from cortical epilepsy, always beginning with abnormal sensations in the left arm, passing to the left side of face and left leg, and at the same time twitchings were present. At first there was no loss of consciousness. At intervals there was great pain in the right frontal region, and a weakness of the left half of the body. There was left-sided hemi-paresis, particularly of the left hand, an increase of the tendon reflex, absence of the ankle clonus and there was moderate double choked disc. Diagnosis: glioma of the middle of the ascending frontal convolution.

September 12, 1891, removal of a tumor the size of a hen's egg.

Microscopical examination showed it to

be a fibro-glioma. Shortly after the operation there was still one attack, after that no more. A careful examination April 3, 1892, revealed an almost normal eye ground, diminution of the sensibility in the left half of the entire body, weakness and stiffness with increased reflex and ankle clonus in left arm and leg.

February, 1893, sensibility had improved. Some muscular atrophy had begun in the left arm and leg.

Of twelve cases of gliomas of the brain operated upon, in six the tumors was not reached until at the post mortem. Of the remaining six, five died usually about one day after the operation. The only cured case was that of *Horsley*, but even this was followed by a fatal return six months after. Of interest in all cases was the unanimous report of the disappearance of the choked disc after the extirpation of the glioma. —W.

## PRIMARY UNION OF A SEVERED END OF THE NOSE.

Dr. Hening, Halle, reports the patient, a student, having fought a duel, which resulted in a complete detachment of the end of the nose. The latter had to be searched for on the floor, and was found about twenty minutes later. It was carefully washed in a solution of ordinary table salt. It was then attached to its former seat with four sutures and bandaged with absorbent cotton saturated in the same solution. During the next twenty-four hours the wound was irrigated with the physiological solution of salt with but short intermissions. The temperature of the solution was kept at 37°.

The entire dressing was changed at the end of the third day. The flap was dark, having occasional red spots. No suppuration; dressed again the same as before, the dressing kept moist with salt solution.

On the sixth day dressing was again changed and the end of the nose began to appear red. The eight day removal of stitches showing primary union. Dressed with boric acid salve.

On the twelfth day the line of union still somewhat red. Otherwise condition excellent.—*Wünch Med. Woch.*, No. 43, 1893. —W.

## SACRAL DERMOIDS.

C. Gussenbauer, alluding to the lack of attention given to this subject in the general text books, has entered into a lengthy consideration in a clinical lecture.

Gussenbauer states that as long as the swelling or tumor is intact the diagnosis is easy; if, however, by some cause (injury, etc.), an inflammation arises which usually results in a fistulous tract, the diagnosis of a tubercular deposit in the sacral region is usually made.

Gusserow recognizes three characteristic symptoms, two of which are, as a rule, present.

1. The presence of one or two dimples situated in the median line toward the distal end of the inflamed swelling. These small depressions are caused by the dipping down of the epithelial layers. As a rule they end in a blind pouch, but may also communicate with a deep seated pus sac.

2. The presence of hair in the fistulous opening, or its appearance in the pus discharged from the sinus. These hairs usually resemble the lanugo and may readily be overlooked if the discharges are not carefully examined.

3. Microscopical examination of the pus usually shows, aside from the hairs and detritus, fatty or horny pavement epithelial cells.

In the presence of the above mentioned symptoms, or should only the last two be distinguishable, they are pathognomonic, and the diagnosis of sacral dermoid may readily be made.

The treatment of an intact tumor of this description is, simply careful and complete extirpation. In cases where fistulæ have formed, it becomes necessary to open the entire passage with the thermo-cautery, then curette the cyst walls, removing cyst walls and epithelium.—*Prag. Med. Woch.*, No. 36, 1893.

—W.

## CONSERVATIVE CÆSAREAN SECTION; THREE YEARS LATER PORRO ON THE SAME PATIENT.

Dr. Rühle, Elberfeld, presented at a medical meeting, held at the above mentioned place, the uterus of a patient aet. 30; third pregnancy; she had a contracted pelvis. The first operation, a conservative Cæsarean section, was performed by Sänger owing to the presence of cicatricial contractions along the vaginal canal. The first pregnancy having been terminated by craniotomy after some futile attempts at version and application of forceps.

The first Cæsarean section was successful in every particular, recovery prompt, the male child living, hearty and well. A drainage tube was passed through the cervix into the vagina in order to drain off the lochia. This opening closed entirely after some time.

The amputation (Porro's method) was performed on October 24th, 1893, before the onset of labor. The patient made a complete recovery, and the child, a girl, is living.

Examination of the uterus shows at the place where the former incision was made, a portion as thin as paper, which would have been the seat of rupture if the operation had not been performed before labor set in.—*Deuts. Med. Zeit.*, No. 98, 1893. —W.

## THERAPEUTIC SUGGESTIONS FROM FOREIGN JOURNALS *

### HEART DISEASE FROM DYSPEPSIA.

Dr. Bucquoi (*Medicinische Neuigkeiten*, No. 50, 1893) points out the value of a certain symptom in the differentiation of those heart affections which are dependent upon dyspepsia. In such patients there is usually a spot in the region of the area of cardiac dullness which is very sensitive to pressure and is situated in the fourth intercostal space. This sign will assure one that the cardiac affection is of dyspeptic origin, and that, by treatment of the gastric disease, the cardiac disturbance will yield. He recommends, in such cases, the use of Hoffmann's anodyne and nux vomica, in the following formula:

℞ Hoffmann's solution,
Tinct. nux vomica, ana,.....5 gms. (ʒj¼).
Ten to twenty drops a day, in a slowly increasing dose.

In order to combat the nervous diathesis which is usually present in these cases, he advises hydropathic measures. Every practitioner will meet, now and then, with cases which, though the patient complains of cardiac symptoms, the cause of their disease ought to be sought otherwhere. They suffer from all sorts of disagreeable symptoms in the precordium, a sense of constriction, dyspnœa, from slight exertion, etc. On careful examination of the heart, in spite of the most attentive search, nothing pathological can be discovered. The sounds are clear and percussion reveals nothing, yet one is not justified in accepting the existence of an organic heart affection nor of angina pectoris.

### PHOSPHATE OF SODA AS A PURGATIVE.

Prof. C. Paul (*Wiener Medizinische Presse*, No. 52, 1893) has employed the phosphate of soda for seven years as a purgative instead of the sulphate, ordinarily used. He prescribes it as follows:

℞ 1. Phosphate of soda.....25 gms. (ʒvj).
Distilled water.....200 " (ʒvjss).
Simple syrup..... 60 " (ʒij).
Alcoholic tinct. lemon .....gtts. xx.

2. Phosphate of Soda,..... 25 gms. (ʒvj).
Distilled Water,..... 250 gms.(ʒviij).
Simple Syrup,..... 60 gm.s(ʒij).
Alcoholic Tinc. of Lemons, .....gtts. xxv.
Citric Acid,
Bicarbonate of Soda, ana, 2gms. (grs.xxx).

About two hours after taking this purgative lemonade an evacuation will take place, which is soon followed by two others. Its action is easy and pleasant and it is taken with pleasure.

### OIL OF PEPPERMINT IN PULMONARY TUBERCULOSIS.

Dr. Carasso (*Deutsche Medicinische Wochenschrift*, No. 49, 1893) publishes a new method of treating consumption with which he claims to have obtained brilliant.

* Translated for THE MEDICAL AND SURGICAL REPORTER by F. H. Pritchard, M. D.

results. It consist in the continuous inhalation of the oil of peppermint, with the internal administration of an alcoholic solution of creasote and chloroform to which one per cent. of oil of peppermint is added. The results were remarkable for, not only were cases cured in the first stage, but also those where there were extensive cavities and numerous bacilli in the expectoration. The cough and expectoration diminish, the appetite reawakens with a considerable increase, in weight, with the growing appetite. Gradually that portion of the lungs affected assumes a normal condition and vesicular breathing reappears. Hence a complete restoration of the diseased tissues to the normal may be assumed to be possible. If the pulmonary affection is associated with fever, it will disappear in a few days. These remarkable results were obtained in no less than thirty-nine cases of actual consumption, in every stage, yet only when it was limited to the lungs and not when other organs were envolved. Braddon has demonstrated that peppermint exercises a bactericidal action and he has also gotten good results with inhalations of peppermint, in phthisis.

---

### SALOL IN PHTHISIS FLORIDA.

Dr. A. Lutz (*Fortschritte Der Medicin*, No. 23, 1893) heartily recommends the methodic use of salol, in florid consumption, from an experience extending over two years. The daily dose was, chiefly, six grams (one and a half drachms), administered in capsules. The fever and night sweats decreased gradually and disappear in a few days to one or two weeks.

The profuse sputum is decreased and the cough diminshed. It will often aid even in desparate cases to prolong life.

---

### DIGITALIS IN FROST-BITES.

Dr. Pilatte (*La Semaine Médicale*, No. 72, 1893,) advises looking to the general circulation in the treatment of frost-bites. They are firstly and chiefly due to a disturbance of the circulation in general, it being a paralysis of the vaso-constrictors from cold. Sanguinary stasis induces partial mortification of the tissues or the formation of fissures and ulcers, this being principally due to a weakness of the cardiac contractions. In those with frost-bites there is a diminution of arterial tension with peripheric vaso-dilation. The mech, anism of this resembles that of Raynaud's disease. Besides treating the basic diathesis—rheumatism, scrophulosis, tuberculosis, etc.—he advises frictions with a hair glove, often preceeded with a cold effusion or douche of short duration. If there be an organic or functional deficiency of the heart then give digitalis, prescribing every week, for two days, seven to twenty-two grains of digitalis leaves, in maceration, caffeine or kola. This former drug yields a remarkable result even in cases where it is not indicated by the condition of the heart It also acts well locally, but then a stronger preparation should be used. Keep the feet and hands perfectly clean, the hands scrupuously dried after washing, and follow with a stimulating friction with eau de cologne or camphorated alcohol. To prevent ulceration or the formation of fissures, use antiseptics locally. Locally, he has obtained the best results with the following formula:

℞ Tinct. digitalis..... 6 gms. (℥ss).
Crystalized Thymol..... 5 (grs. xlv).
A'cohol .. ..... (70 per cent.).
Glycerine.....ää.... 150 (℥ivss).

In case of severe itching apply locally the tincture of iodine, every three to four days. Fatty substances and vaseline are to be avoided while gloves and warm baths are more harmful than useful.

---

### SCARLATINA IN CHILDREN.

Dr. A. Correa (*La Semaine Medicale*, No. 72, 1893) praises in scarlatina of children, the following:

℞ Nitrate of pilocarpine..... 3 gms. (grs. xlv).
Aconotine.....3 gms. (1–20 gr.).
Salicylate of soda.....¾ gms. (grs. xlv–℥j).
Alcohol,
Syrup of orange peel, aa...15 gms. (℥iv).
Distilled water.....120 gms. (℥iv).

A teaspoonful every twenty minutes, until the usual effects of pilocarpine are noticed. As soon as this action disappears then commence its administration again. He claims that under the influence of this method of treatment the disease, even in case that it be malignant or associated with pultaceous angina, assumes a benign character.

---

### ICE IN ASTHMA

Dr. Sangee (*La Semaine Médicale*, No. 72, 1893) in a violent seizure of bronchial asthma where all the usual remedies were powerless to abort the spasm, succeeded in relieving the attack by local application

of ice to the neck, along the course of the pneumogastric. Five minutes after its application the asthma disappeared entirely and the patient fell asleep, for the first time, after four nights of complete sleeplessness. At the end of several hours he was awakened by the sensation of severe cold produced by the ice. It was then removed and replaced by compresses, under which influence the last symptoms disappeared entirely.

### CORYZA.

Dr. Grellety (*La Semaine Médicale*, No. 72, 1893) speaks highly of the following formula, in the treatment of coryza:

℞ Betol, 2.50 gms..... (grs. xxxviij)
Menthol. 25 cgms..... (grs. iv)
Muriate of cocaine 15..... (grs. ijss)
Powdered roasted coffee, 1. 50 gms. (grs. xxij)

This should be finely pulverized and passed through a fine seive.

### GLYCERINE IN GRAVEL.

Dr. Heymann (*Revista de Ciencias Medicas de Barcelona*, No. 24, 1893) has employed glycerine in renal lithiasis, on account of its property of dissolving uric acid and also passing unaltered through the kidneys. He records fourteen cases treated by this method. He summarizes his impressions as follows:

The first effect of its ingestion is to increase the thirst. In those suffering from stone in the kidneys, pains appeared in this region, it being limited to the one side affected. The quantity of urine was increased, and, after a varying time of nine to twenty-four hours, small calculi were expelled. In ten out of these fourteen cases he obtained favorable results. The pains were not as severe as those of renal colic while the urine, after its ingestion contained neither albumen, sugar nor hemoglobin. Even after three to four hours the presence of glycerine could be discovered in the urine, in appreciable quantities. A large quantity of mucus was also noticed. Based upon these results he regards glycerine as the most efficient means of treating renal lithiasis.

### BICARBONATE OF SODA IN DIABETIC COMA.

Prof. Huchard (*Revista de Ciencias Médicas de Barcelona*, No. 24, 1893.) calls attention to the value of the bicarbonate of soda, in large doses, in the treatment of diabetic coma. The precursory symptoms somnolence, dyspnœa, and muscular weakness, all disappear within a week, if one administer increasing doses of the bicarbonate thirty to forty-five grams, an ounce to an ounce and-a-half, per diem. He cites a case, treated in this manner, which confirms the value of this method. The vertigo, mental depression, anuria, disappeared in forty-eight hours after the administration of twenty grams, five drachms, of this salt. Although the hypodermic use of alkalies has not given good results in the treatment of acetonnuria he thinks that the opportune employment of the bicarbonate, during the prodromal period, to be a precious addition to our treatment of diabetes.

### DIARRHŒA OF DENTITION.

In the (*Ciencias Médicas de Barcelona*, No. 24, 1893), in the treatment of the diarrhœa of dentition, the following preparation is found of use.

℞ Subnitrate of Bismuth.....4 gms. (ʒj.)
Lime water.....8 " (ʒij.)
Fennel water.....100 " ʒiijss)
Syrup of Orange Peel.....20 " (ʒv.)

One teaspoonful every three hours.

### FETID DIARRHŒA IN CHILDREN.

Dr. E. Tompkins (*La Semaine Medicale*, No. 73, 1893) speaks highly of the following, in the fetid diarrhœa of children as an intestinal antiseptica.

Calomel ..... 10 cgms. (grs. jss).
Sulpho-carboate of Zinc..15 " (grs. ijss)
Subnitrate of Bismuth.. 8 gms. (ʒij).
Pepsin..... 2 " (grs. xxx).

Sufficient for twelve powders. Three per diem, in a child of one year.

### ABSORPTION OF SALICYLIC ACID BY THE SKIN AND ITS USE IN ACUTE RHEUMATISM.

Dr. Bourget (*Revista de Ciencias Médicas de Barcelona*, No. 24, 1893) concludes as follows:

I. Absorption of salicylic acid by the skin is very rapid and intense. The skin of youthful individuals is most absorbent while persons with white skins are more so than those with brown or black. The rapidity and intensity of its action are dependent upon the vehicle in which the acid is dissolved. Fatty substances greatly facilitate its penetration through the skin while with glycerine or vaseline it is less. Treatment of acute articular rheumatism with a salve of salicylic acid and turpentine is to be recommended. It is less serviceable in other forms of rheumatism though it might be of value as an adjunct in massage. In gonorrhœal rheumatism it is inactive.

# THE MEDICAL AND SURGICAL REPORTER

ISSUED EVERY SATURDAY

Address care P. O. Box 843, Philadelphia, Pa.

HAROLD H. KYNETT, A. M., M. D.
Editor

RODERIC C. PENFIELD
Publisher

147-149-151 North Tenth Street, Philadelphia

TERMS:—Three Dollars a year, strictly in advance. Sent four months on trial for $1.00.

REMITTANCES should be made payable only to the Publisher, and should be made by Postal Note, Money Order or Registered Letter.

NOTICE TO CONTRIBUTORS:—We are always glad to receive articles of value to the profession, and when used they will be paid for, or reprints supplied, as the author may elect. Where reprints are desired, writers are requested to make a note of that fact on the first page of the MS. It is well for contributors to enclose stamps for postage, that the articles may be returned if not found available.

SATURDAY, FEBRUARY 3, 1894.

## EDITORIAL.

### A WISE PROPOSAL.

Evidently anticipating its opportunity, the *Medical News* denounces "The Star System of Medical Education" and urges radical changes in the organization of medical faculties. It believes that "the organized and vivified medical college is to take the place of the cluster of individual medical star-professors of the past—that personalities are to be subordinated to a system, leading rôles to be merged into a harmonious unity, men into an institution. A great work is to be done, a work requiring a large number of specialized workers, each performing his peculiar function, each the equal of the other, and all running to a unity of result that leaves no place for exaggerating one or two rôles, while extinguishing all others. It is clear, therefore, that the college which soonest and best meets the new ideal will be the college of the future, and the college that clings to the methods of the past, seeking a few leading actors and cruelly silencing subordinates—with necessarily resulting jealousies and self-seekings—must assuredly go down. Such a college as this last inevitably becomes ring-ruled, the financial aspect ever uppermost, never willingly lengthening the course or raising the entrance standard."

It concludes its attack on the present order of things as follows:

"This new tendency, nay, this coming and pressing necessity, does not in the least extinguish individuality, but leads to its healthy development. It was the old plan that with ruthless barbarity throttled all individuality except the egregiously selfish individuality of the star, and that smothered nascent ambition and possible teaching ability in order not to permit rivalry. The new plan, with its enormous increase in numbers of the teaching body of a college, encourages the healthy growth of individuality and of special ability. But it does one other most important thing: it reduces to useful subordination all egotistic advertisers and self-seekers, and binds individualities together for a work and a system that outlasts and is of more importance than individuals."

We do not understand that the new dispensation advocated, contemplates the utter extinction of stars of the first magnitude in order that the glimmerings of the milky way may become manifest, but rather the turning down of those flickering gas-jets which, intruding in the field of vision, obscure all other lights, and which in certain conditions of mental fogginess, have been frequently miscalled 'stars.'

It means the suppression of 'stars' which in reality are only reflectors of light gathered from extraneous sources, which sources are studiously concealed from the public view. It intends the abolition of 'professors,' whose greatness consists in an unlimited capacity for *unconsciously assimilating* the ideas of modest thinkers and, *consciously* ignoring the sources of their ideas, promulgating them as their own. It means the sequestration of authors and authorities who buy the work of starving brains and publish it over their own names.

In all branches of science reputations obtained by furtive means are numerous —and evanescent. It is the elimination of such 'stars' that is proposed and the substitution therefor of a galaxy of fixed stars, each occupying its own place and shining by its own inherent light. All acting in harmony, to constitute a constellation which when sought for can always be found, and which affords a basis for accurate calculations.

Coming down from the clouds, this means that the faculty of a medical college should be made up of *teachers* thoroughly acquainted with the subjects which they are to teach and capable of imparting their knowledge to others. It means that these men should be afforded every facility for conveniently prosecuting their studies. It means that they should make the interests of the institution their own, and should not subordinate the institution to any outside interests. It means that these teachers should be secure in their positions so long as they perform efficient work. It means that they should be allowed to think for themselves and to have the freedom of speech. It means that each should be the peer of the others, and that the will of the majority should determine the policy. It may mean a good deal more on these lines, but in effect it presents one side only of the question.

The *Medical Record*, commenting on this article in its usual light-hearted manner, tersely presents the other side. It says:—"There is no doubt that too many medical men become "professors" from purely selfish motives, such as building up a consultation practice, or posing as "eminent authorities" before the laity. On the other hand, unless "professorships" are made attractive and profitable, the best talent will not be eager to enter the charmed circle of professorial dignity. Human nature is not materially altered by the possession of a medical diploma. Unless professorships "bring in" something tangible, only mediocrity will stampede toward the empty honors of the college chair. Good men demand good rewards in this matter-of-fact world. Emoluments are just as attractive to doctors as they are to lawyers, or to clergymen, or to plain every-day business men. The professor of the future may not care about sordid details of compensation for his work. But we take it that that kind of professor is a dim and nebulous hypothesis, whose chair is not planted on terra firma. A flesh and blood professor needs his three meals a day, just like ordinary mortals. And we believe, in most instances, he deserves them."

In other words, secure the best teachers, appreciate their value and pay for their services. Services that can be obtained for nothing are worth less than the price paid for them.

It will be noticed that there exists a distinction with marked differences between *teachers* and *professors*.

## RESPECTFULLY DECLINED.

The *Record* concludes its comment on the preceding article with an exhibition of disingenuous generosity that is awe inspiring.

"If they really need more professors over there in Philadelphia, we might, on a pinch, let them have a few of our own. A famine of professors is not what we are seriously threatened with at present in New York."

More professors!" Angels and Ministers of Grace defend us!" If by the most violent squeezing a few efficient *teachers* can be extracted over there, Philadelphia can furnish them a field for work and contemplate the gift with equanimity. But as the lack of such material is much more painfully evident in New York than here, we must respectfully and firmly decline to have any more "professors" unloaded on us. However glad to accommodate friends, Philadelphia must enforce the first law of nature.

So far from there being in this city any lack of 'professors,' our factories annually produce more men with professional qualifications and aspirations (as can be certified by every member of their immediate families, relatives by blood or marriage, or any socially connected with them, their domestics, employees or clubmates) than the entire number of professorships existing in the United States. What Philadelphia does lack is cold storage facilities for the safe keeping of 'professors' for the benefit of posterity.

Efforts have been made to meet the conditions, but the problem appears to be similar to the social question of the treatment of the unemployed, but on a much reduced scale. Some institutions have experimented by taking a "chair," none too large for a single teacher, dividing it, and constructing two or more high chairs suitable for *professors*, imposing a high tariff for revenue and installing the most needy applicants.

The results of such speculations appear to have been more for edification and less for education. The cost of chairs seems to have grown beyond the reach of private resources, and now require a subsidy from the government to maintain them. Indeed, it looks as though 'professors' would soon require a congressional appropriation (either under a River and Harbor bill, or a deficiency appropriation) to secure an opportunity for letting men see their light shine. 'Professors' are too numerous and chairs cost too much, and we don't want them anyhow, but for higher medical education and the progress of medicine, we do want more efficient *teachers*, and we wish to see them paid for the value of their brain-work and not for ability to make excerpts from the ancient chronicles of medicine.

### Creasote in Chronic Pyelo-Nephritis.*

Dr. Weber (*La Semaine Medicale*, No. 72, 1893) has found creasote of value in the management chronic pyelo-nephritis. In this disease, consecutive to renal lithiasis, gonorhœa or other infectious disease the condition of the patient is often very grave and frequently incurable, for, as in pulmonary tuberculosis there is a progressive exhaustion. In certain cases surgical measures as nephrectomy or nephrotomy may render efficient aid but it often happens that these very operations are impractical, as for example, when the hydronephrosis is bilateral, the patient is either too aged, too weak or refuses an operation. The usual medical treatment is generally quite unsatisfactory. Creasote administered, internally, for a long time and, in large doses, will yield favorable results. In four cases, treated thus, he has obtained a distinct and lasting amelioration, after a few months of treatment. The attacks of fever, together with the painfulness, in the region of the kidneys, disappeared, micturition became clearer and continued less and the patients felt well, while there appetite increased together with their weight. He administered the remedy either by the mouth or rectum in injections or suppositories—in doses of three to five drops, three times a day.

# ABSTRACTS.

## THE PHYSICIAN AND THE PHARMACIST.

In a paper read in the Section on Materia Medica and Pharmacy of the American Medical Association. Dr. L. Ch. Boisliniere says: A few words of protest and advice are herein offered from an old practitioner. I believe in the profession of pharmacy and I highly respect the pharmacists. They are the hand-maids of the physicians and our best friends, often our useful advisers. The two professions should work in harmony, one not encroaching upon the specialty of the other. Therefore the pharmacist should not tolerate any counter-prescribing, and the physician should not dispense his own medicines. I therefore most strongly protest against the custom, lately too frequently resorted to by physicians, of distributing among their patients any of the potent triturates, or dosimetric granules, so elegantly put upon the market by otherwise reliable wholesale dealers. This practice is enticing, but it is often dangerous.

This protest applies chiefly to the city physicians; an exception should be made in favor of the country practitioners. For them it may be sometimes absolutely necessary and is often very convenient; they are so placed that they can not do otherwise; but it is a practice fraught with danger.

This practice, in cities especially, may be followed by suits for malpractice in case of any accident. The prescriptions on file with the pharmacist are a strong protection to the physician, as they can be referred to, and, if necessary, brought into court in case of a suit for damages. While serving as coroner of St. Louis county, several cases of this kind came under my official notice for investigation. One was the case of a woman, for whom a most reputable physician had prescribed a mild cough mixture. The husband, at the inquest, stated that his wife walked in the garden, after taking a teaspoonful of the medicine, and dropped dead, as if shot. Happily, the bottle of medicine was in the house, properly numbered, and came from a very good pharmacist. The prescription from the file was brought to the house of the deceased and shown to the jury to be a harmless mixture. This, however, did not entirely satisfy the husband. In order to convince him, I opened the deceased's chest and showed him the heart; the pericardium was enormously distended; puncturing it, I received in a cup nearly a pint of serum. The woman had died of acute pericarditis. This amount of serum, pressing on the heart, had caused its sudden stoppage and the patient's death. The husband was satisfied and the physician discharged.

Upon another occasion, an old man had had a weak solution of morphia prescribed for nervousness. The next day I called at the house and found the front parlor full of people and crape at the door. On my inquiring about the patient his sister rushed in, in a fury, and exclaimed to me: "You dare inquire about my brother! You killed him! He walked to the mantelpiece, took a teaspoonful of your infernal mixture and dropped dead!" He died of paralysis of the heart, as was afterwards ascertained. The pharmacist, an excellent one, was requested to come immediately with the prescription, which he had on file, and which called for one grain of sulphate of morphia, of which the patient had taken one teaspoonful, equivalent to one-eighth of a grain, which certainly is not a poisonous dose. The family was finally satisfied that the fatal result was not connected with the medicine.

From these cases is seen the great advantage of filing, dating and numbering prescriptions.

In another instance, there was prescribed for a young woman a one-eighth grain dose of morphia; but, through the accidental misplacement of the bottle, she took one teaspoonful of strong sulphuric acid, and would have died had it not been for copious draughts of water, mixed with plaster scraped from the walls of the room. For several months, she could swallow nothing but milk, as she had an extensive inflammatory stricture of the esophagus.

Here the pharmacist was called in to show that the prescribed mixture was a weak solution of morphia and not sulphuric acid, which it was subsequently learned had been left carelessly in the room to acidulate a battery. I could relate more cases, but these are sufficient to illustrate my position, that often the pharmacist is the best protector of the physician.

Another point to be considered is this: Quite a reprehensible custom is that of pharmacists, on demand of patients or their friends, repeating prescriptions without the order of the physician. This is done generally because it would be impolite to refuse; moreover, they have nothing to gain by it. This indefinite refilling of prescriptions should not be done, because it makes the patient his own prescriber, often to his own detriment, as no two patients or diseases are alike. It is a dangerous practice, and should be abolished by a mutual agreement with the pharmacists. This practice is often resorted to by designing persons for mercenary purposes. I will briefly recite a case to illustrate:

I once prescribed a mild but efficient cough mixture. What was my amazement when I ascertained that the formula had been printed and sold to many acquaintances for twenty-five cents a copy. Let, then, physicians and pharmacists live in perfect harmony, following their useful and noble professions, each respecting and protecting the other. — *Jr. A. M. A.*

## THE SUCCESSFUL MANAGEMENT OF INEBRIETY WITHOUT SECRECY IN THERAPEUTICS.

Dr. C H. Hughes, (*The Alienists and Neurlogist,* January, 1894,) writes: Dr. Benjamin Rush, in his "Diseases of the Mind," published in 1812, recommends, "The establishment of a hospital in every city and town in the United States for the exclusive reception of hard drinkers" and says "they are as much objects of public humanity and charity as mad people; and religious, moral and physical remedies * * * should be employed * * * for the complete and radical cure of their disease."

Since the immortal Rush rested from his labors, vast progress has been made, and vaster still is making in the management of the drink habit, and in the treatment of the drink disease. Facts which, but a few years ago advanced observers, like Morel, Magnan and the few neurologists of their time, first took note of, touching the hereditary transmission of neuropathic instability and dipsomaniacal tendencies through ancestral alcoholic excesses and *vice versa,* have not only passed into the possession of the profession generally as practical knowledge, but have become largely the mental possession of the people. The profession, the people, and even the unfortunate victim of the drink habit himself, have come to the understanding that habitual resistless inebriety is a disease and chiefly of the brain and nerves, and under this impression, resulting from medical research and teaching, the drunkard and the dipsomaniac now seek and the profession now give, medical relief to the sufferer, or the friends of the inebriate procure this relief for him.

The general professional consent and popular recognition of the fact that inebriety is a disease, are the results of the impressive and persistent efforts of the British and American Associations and other medical societies having in view the cure of inebriety.

In the general recognition of the fact of the disease basis and remedial possibilities respecting the baneful, morbid vice of the man's nervous system, we are hopeful of such an inestimable physical and moral fruition as must ultimately result in marked national re-invigoration, and in the postponement, at least, of national degeneracy impending through this, as one of the causes of racial decline.

We know now how to successfully scaffold and prop, and steady the tottering nervous structure of an inebriate neuropath, and sustain it in fairly normal function pending its effectual reconstruction, and we know how to permanently rebuild this damaged nervous system, through the advances neurology has made during the life of the present generation of physicians,

though, alas, we cannot always remove the baneful neuropathic entailments of chronic alcholism upon the immediately succeeding generations of the drunkard, while we may and do, do much to ameliorate, modify and ward off the baneful neurotic *sequelæ*.

The unchecked degeneration of whole families through generations of neuropathic descent, such as Morel and others have presented, as the frightful admonitions of scientific research against the fatal neural and psychoneural degeneracy of alcoholic excess, are not possible under the skillful management of modern medical art as now practiced, especially in the neurological department of medical work.

It may profit us at this juncture to recur again (as mentally we often do to similar personal observations) to one of Morel's typical tables illustrative of the course of alcoholic neuropathic degeneration unassisted by our art, and I take this table from our classical and observant *confrere* across the ocean, Dr. Henry Maudsley, because the interesting researches of Morel into the formation of degenerate or morbid varities of the human race have served to furnish to the physiological mind of this distinguished neurophysiologist, as it has to you and me, a philosophical view of the chain of events by which alcoholism as a cause of individual degeneracy continues its morbid action through generations and finally issues, when unchecked by the arts of our profession, in extinction of the family.

First generation.—Immorality, alcoholic excess, brutal degradation.

Second generation.—Hereditary drunkenness, maniacal attacks, general paralysis.

Third generation.—Sobriety, hypochondria, Lypemania, systematic mania, homicidal tendencies.

Fourth generation.—Feeble intelligence, stupidity, first attack of mania at sixteen, transition to complete idiocy and probable extinction of family.

How many painfully impressive pictures like this have we not seen in our several spheres of observation and practice, and how many impending family calamities like this are now avertible through the resources of medicine and philanthropy which our present advanced neurology offers the neuropathically unstable? It is a source of professional congratulation that the medical profession, and especially our department of professional endeavor, has brought relief to the inebriate, and mitigation with the hope of ultimate extinction of its entailed neuropathic evils to the human family, if only we are permitted to treat this disease as its pathology demands, and an enlightened public sentiment promises this as the consummation of our professional labors and hopes in behalf of man's highest and best interests for the closing of the Nineteenth Century.

The profession and the public believe that inebriety is a disease. They now believe that it can be successfully treated, and that it ought to be treated, not only for the good of the inebriate, but for the welfare of his descendants. They have now the knowledge that precedes wise action.

Drunkenness is unpopular; inebriety is on the decline; dipsomania is dangerous to the drunkard's descendants, as well as detrimental to himself.

Medicine has given to the world the substantial basis of a new reformation. It has sounded the alarm; it offers the remedy, and, on this score, we think humanity is on the road to safety.

This is one of the jewels we place in the crown of the Nineteenth Century progress. We give it freely to the cause we crown without copyright, letters patent or secret process.

With the diffusion of knowledge among the people and their advisers, the general profession, and especially the family doctor, that alcoholism and dipsomania are grave diseases, with graver physical and psychical *sequelæ*, hope has dawned for the drunkard, and the prospect of the final obliteration of inebriety and its terrible evils to the individual, the family and the state, brightens. Henceforth, the unfortunate victim of alcohol is to be cured and then reformed through the seeking of medical relief, and such as are not confirmed in baneful habits of intemperance will turn in time from the social tempter, and avoid the neuropathic thraldom of this devil's chain of evil tyranny.

Many men who fall into the drink habit are unaware of the terrible neuropathic heritage of unsteady nervous organism bequeathed through bibulosity and other nerve depressing influences operating on their ancestors. They know but little of the organic evils and entailments of alco-

hol. They know chiefly physical, moral and social discomforts and inconveniences of getting drunk, which are as nothing compared with the damage to their brains, nervous systems, blood-vessels and vital organs.

Not understanding the tyranny of their unstable nervous system they censure themselves as fools for each repetition of a bout of drinking and resolve and re-resolve not to do it again, then go on and die the same, in the majority of instances, unless aided by medical art to overcome the otherwise resistless tyranny of a viciously endowed organism, which impels to the fate they dread without the power to draw away from it, yet thinking each time they drink it will be the last.

The trouble in the past about this blended vice and disease has been in the failure to seek, by suitable change of environment and proper medical treatment, that renovation and rebuilding of the damaged organism which makes resistance to alcoholic enslavement a possibility in the organism of the average habitual or periodic inebriate. That profession which has rescued mankind from so many portentous evils after other resources have failed, is ready to succor him now from the thraldom of damaged organism and psychical weakness and neuropathic instability.

We need not now go deeply into the pathology of chronic alcoholism, but cursorily glancing at the subject we have only so recall the findings of Virchow, Richardton, Horsley, Percy and Binz, of water decreased and fibrine changes in the blood, sometimes quite fluid, at others, coagulated, pure alcohol in the tissues, fatty globules in the circulation, fibrinous clots and excrescences in the vessels, vascular dilations, anæmia, deficient hæmoglobin, of old and excessive alcoholics.

Nor need we dwell upon other destructive and degenerative changes, which, like the annihilated phagocytes of alcoholized persons to which their well-known lack of resistence to general morbific influences is due, are secondary to the poison. We have to treat these conditions as *sequelæ*. This fact and the other prominent fact that alcohol abstracts fluid from the tissues of an organism whose very nerve cell is bathed in lymph, whose cerebro-spinal axis, as Obersteiner tells us, lies in a sea of lymph, an organism to which water is the *sine qua non* of life, give us the chart and compass of our course; and the polar star is the care and cure of the damaged brain, the brain and associate spinal and ganglionic system from whence originates the illusions, the hallucinations, delusions, anæsthesias, paræsthesias, hyperæthesias and hyperalgæsias or the peculiar polyæsthesias of these cases. All of these sensory troubles, together with the well-known motor symptoms, the motor paresis, muscular tremor, twitchings and inco-ordination, the *paresis* of the cortical areas of the brain, where the volitions center and whence they proceed, impaired and vitiated, in the drunkard. To these and other symptoms which go to make up what Bevan Lewis designates as the motor anomalies of an alcoholic etiology and all the psychical symptomatology, which this writer and Huss and Magnan and Maudsley, Usher, Wilson and many others describe, give us adequate outline of the detail work necessary for the thorough and permanent cure of the inebriate. He will be largely made over and made whole. No three weeks' treatment will suffice. We may break him for the time of his habit in three weeks and yet leave him a wreck for life. Our duty is to repair him and make him anew if he will permit us to do it. We cannot ignore the protean nature of alcoholic symptomatology or forget the fact in our treatment of this disease that no poison except the virus of syphilis plays so extensive a *role* in the morbid affections and degenerations of the tissues, nervous or non-nervous, as alcohol.

When illustrated chapters in the pathological anatomy of alcoholism, especially like those in Bevan Lewis' recent textbook on "Mental Diseases," are so readily accessible, and when, besides, the cultured character of my distinguished auditors is considered, it is obviously unneccessary to dwell in detail on the pathology of alcoholism. I could not enlighten you—you would rather enlighten me on the subject.

The point of this paper is psychcial assistance and neurotic support, and neurotic and organic reconstruction. We must first secure the man's safety from the thraldom of drink and repair the secondary damage later. We must first put out the fire and save what remains of the still standing structure, prop the weakened walls, and then rebuild and re-

move the damages. The foundation and framework of all reconstruction of the drink-damaged dipsomaniac is in the nervous system. If we can rescue that from immediate and ancestral damage, we can save the man, but we must not leave him, after our treatment, damaged and shattered in his brain or nerves or blood or vital organs. We must make him strong and resistive in the higher inhibitory volition and directing realms of the cerebral cortex and restore the normal functions within and presided over by the lower cerebro-spinal and ganglionic centres.

It is obvious that in attempting to effectually and permanently cure and reform the inebriate we undertake a large contract, one that cannot be fully complied with in the brief space of a few weeks. When we have broken the chain of morbid habit there yet devolves upon us the duty of after-care that the victim's health may not be permanently shattered, and that insanity and other evils may not follow.

*The first* essential to the cure of inebriety is the substitution of a less harmful support to the shattered brain, nerves and damaged vital organs, than alcohol, and I name them in their order of preference. The morphias or opium, strychnia, the quinias and cinchonias, valerianates, cocas, the ammonium bromide, etc., etc.

*The second* and concomitant essential is water—plenty of water or its equivalent, milk. The tissue must have water, the blood must have it, the emunctories and the skin must have it.

*The third* and concomitant essential is rest. Normal nature tired prescribes it for every bodily or mental overtax. Exhausted abnormal nature always needs it and demands it often. The machinery of the human orgamism in all its parts—psychical or physical—must be put at rest for the best repair.

The chief essential for rest is a new and proper environment, and subsidiary to this are the chemical restraints therapeutics may place on over-acting cells; chloral, sulphonal, the bromides, the vegetable narcotics, old and new, the valerianates, the opiates, cephalic galvanization, and soothing music and the bath.

*The fourth essential* is the removal of the *debris* of the last and previous drunks, and of the interim of organic torpidity and depressed vitality. The scavenger cells, diminished in number or absent as they are in *toto* from the blood, and the emunctories have failed in their physiologically appointed work; the congested brain, liver, stomach, intestinal tract, mucous membranes generally, torpid liver, bowels and skin, are to be relieved and set at their proper work again.

Here, water, saline laxative water without stint, is the remedy *par excellence*. It flushes the intestinal tract and the excreting organs. Nature suggests it first of all after the rest she enforces after a prostrating spree.

I need not here dwell on the proper therapeutic blendings for this hydrotherapy to give more special direction to liver, kidneys, skin or bowels.

My preference is for an effervescent salines that clears out the alimentary tract and tranquillizes the brain and nerves at the same time (though mercurials are often not amiss), and then to properly start all the pumps of the system that may not be acting well and maintain them in moderate activity till there remains no pathological clogging of the wheels of physiological activity, but I do not approve of over-active catharsis. Moderation and not violence in this regard is my motto.

The *fifth* and concomitant essential is reconstruction of the undoubtedly damaged cerebro-spinal centers and the several affected organs of vegetative life. A drunkard is more or less damaged in many parts of his anatomy at the same time. He comes more nearly to being affected all over in spots than most patients we have to treat.

We begin reconstruction with the beginning of treatment. It begins with rest and sleep and food and change of surroundings, when Nature, without further aid, can effect it, rest, nutrition and phosphates, the hypophosphates and the reconstructive hæmatics and other rebuilders of the blood. Milk, beef-tea and capsicum and other stomachics. Early in the treatment a hair of the dog that bit him—a milk-punch or egg-nog, egg phosphates flavored with wine or whiskey, the latter soon withdrawn. In this stage the wines of coca, the beef, wine, iron and strychnine compounds, calisaya cordials, egg phosphates and stimulant tonics, are temporarily admissible.

When the patient is cured of his recent attack of delirium tremens, or recuperated from his last debauch, then the hypodermic medication that is to hold him from further relapse, to re-tone his system and break him of his taste, must be instituted, if we have not begun it sooner.

*The sixth* and final essential, to which all our previous efforts lead us, is destruction of the drink craving, and this is done on physiological principles. The drink craving is pathological perversion of physiological cell action, and lies in the realm of the cerebral cortex. This part of our subject belongs to psychiatry and psychical suggestion, effected by a therapy directed to these morbidly acting centers of the brain, accomplishes our purpose. When the drink craving comes on, having in the meantime rebuilt the shattered brain and nervous system and restored the mental tone as much as possible, we do not absolutely inhibit the use of the accustomed drink, but train the drink victim's own inhibitions, first, by suggestion; second, by moderate indulgence properly treated.

We do not say, "You shall not, but you had better not drink. You know it is poison to you and you are its slave. You should resist. Your treatment has made you strong. You *can* resist. Whiskey no longer tastes as good to you. You no longer need it. You have the power now and should assert your manhood," and with these suggestions, perhaps the victim will try the liquor, we give him *spiritus frumenti* f℥ij, *cum vini antimonii*, f℥i, and repeat *ad libitum*, or we have previously given him apomorphia with aurum bichloride for psychical effect. Under this or similar management of the appetite, the victim acquires a disgust for his favorite drink, he discovers his inhibition of the propensity is strengthened, and a disgust supplants the taste, which abides till he is fully restored in nerve tone and power to permanently resist and assert his manhood and maintain it against all future assaults of the foe.

As I cannot, in the brief time allowed, further detail my plan of treatment, this outline must suffice, with the promise in another communication of special prescriptions and combinations, embodying the plan of treatment here outlined, and which has proven successful in desperate cases.

After your patient is cured, after the toxic effects of alcohol have gone from the blood, and the higher and lower nerve centres and the damaged tissues of the body have regained their normal nutrition, powers of assimilation, and strength of physiological action and resistance; after confidence in his strength has returned to the patient, he must be warned to never again have confidence in his power of resistance with alcohol in his blood. Let him that thinketh he standeth then take heed lest he fall again. The cure of the drink habit is not always perpetual; it is not everlasting without the aid of the patient himself. Though to some the appetite never comes back, to others it is not safe to trust it with temptation. So that the safe plan, since no inebriate fully knows the full extent of his own inherent organic instability, is to "touch not, taste not, handle not," ever after. His treatment leaves him strong enough say "No," and "Get thee behind me, Satan," to his tempter. It does not alway leave him so strong that he can take the tempter to his bosom. He cannot always try a tussle with the tempter and not be thrown.

### The Drainage of Pyosalpinx Through the Uterus.

In a paper read before the American Gynecological Society, Dr. Murray joins with Dr. Polk and others in claiming that pyosalpinx can be cured without resort to the removal of the offending organ. The patient must be anasthetized, the uterus dilated, and then thoroughly curetted. He formulates the following conclusions:

1. That many cases of pyosalpinx are curable without mutilating operations if the endometritis be treated by curettage and drainage with strict antiseptic percautions.

2. That uterine curettage and drainage should be practiced in every case before operation unless the tubes are very distended and thin, to cure the endometritis which may be and often is cause of trouble and of the lack of relief after celiotomy and removal of the organs have been performed.

3. That even after pyosalpinx frequently the tubes and ovaries are not useless organs, the proof being that pregnancy occurs and the puerperium is normal.

4. That only after proper treatment, the tubes, ovaries and uterus still remaining bound down by adhesions and continuing a menance to life and health, should the radical operation be done.—*Pacif. Med. Jour.*

# SOCIETY REPORTS.

## THE LOUISVILLE CLINICAL SOCIETY.

*Meeting December 5th, 1893.*

Dr. L. S. McMurtry read a paper on

HYSTERECTOMY.

(See page 159)

VIOLENT CASE OF LA GRIPPE.

DR. T. P. SATTERWHITE: I would like to ask the members of the society if they have seen any violent cases of the fashionable disease "La Grippe." The reason I ask is that a week ago last Sunday I was called to see a lady who is about six months advanced in pregnancy. She was perfectly well the day before; in the morning she felt a little indisposed and about two o'clock she was taken with violent coughing and constriction through the chest. I saw her about four o'clock in the afternoon, and thought she was a little cyanotic. Her respiration was about fifty; pulse 130; there was no fever, but incessant coughing. I gave her a hypodermic injection of morphine and wrote a prescription for some simple remedy and left. About nine o'clock Sunday night I was summoned, and found her decidedly cyanotic; pulse 140, but no fever. I should have stated that on my first visit, in an examination of the chest I detected some crepitation, but as there was no fever of course I excluded pneumonia, and thought possibly it was pleurisy. I asked her if she would allow me to bleed her as I thought it would give immediate relief. She consented to the procedure, and I drew from the arm probably about a pint of blood which was followed by immediate relief of all oppression in breathing, and she expressed herself as feeling very comfortable. I did not draw as much blood as I wanted to, from the fact that she said she began to feel a little sick, the current had about stopped and I did not want her to faint, consequently I put my finger over the blood vessel and stopped the flow. She had after that coryza; at no time was there any elevation of temperature, but all symptoms for some days afterward of influenza, and I thought probably it was one of the manifestations of grippe.

DISCUSSION

DR. C. SKINNER: About a year ago Dr. Bailey asked me to see a woman with him. He had just delivered this woman at full term, of a perfectly healthy baby, and the patient had been well up to the time of beginning of the labor. She had a normal, easy and quick labor, but immediately upon the termination of the labor, even before the placenta was removed from the vagina, she developed the identical chain of symptoms detailed by Dr. Satterwhite: extreme difficulty in breathing, fullness of the chest, incessant coughing, etc. Her mouth would fill with mucus as fast as she could throw it off. I saw her just at this time, and we remained there all through the night. Under the administration of whisky, occasionally with ammonium, the symptoms gradually subsided. She was not a plethoric woman at all. By morning she was feeling very comfortable. There was no expectoration of blood, but there was an excessive accumulation of mucus that interfered with the respiration. Her recovery was complete.

SUCCESSFUL CASE OF VAGINAL HYSTERECTOMY.

DR. W. H. WATHEN: A few weeks ago I reported to this society, three successful cases of vaginal hysterectomy. To-night I will report another recently performed and which will make an uninterrupted recovery. In my work in vaginal hysterectomy for malignant disease I have lost but one case; that was three years ago, and resulted because of ignorance of the necessity of thoroughly curetting the necrosed tissue away before attempting the hysterectomy. Since then I have had no trouble, and my patients recover without sepsis.

The patient is an elegant lady of nervous temperament, and has never been a strong woman. I treated her several years ago for some uterine or pelvic trouble. On her recent return from Europe, her family physician called me in consultation to see her. I diagnosticated cancer of the cervix, which had existed to an extent to attract her attention for six months. The cancerous mass in the cervix which was larger than a hen's egg, was thoroughly curetted and left for two weeks before an hysterectomy was done. By this time the tissues had contracted so that the ulcerated surface was no larger than a nickel, simplifying the operation and doing away with the danger of sepsis from the necrosed tissue. The cervix was again curetted immediately before the hysterectomy was performed. The uterus was easily removed and the broad ligaments were clamped; no sutures were used. It required but two clamps to control bleeding and the patient did not lose over one-half ounce of blood. In my previous hysterectomies I was compelled to use more than two clamps. Sometimes ligatures were also applied. She had no shock, vomited but little, and the pulse did not go above 65 for nine days, and there was no elevation of temperature. But on the tenth day, from imprudence in eating, she had indigestion and the pulse was 100 and the temperature 101° F. for six hours; she

has since continued in a normal condition. I wish to emphasize the fact that as a result of the operation, the temperature was not elevated nor did the pulse go above 65.

Vaginal hysterectomy is primarily one of the most successful of all capital operations. I do not think it important whether we use clamps or sutures, and the results will be as good with one as with the other.

I was recently interested in reading the report of a series of hysterectomies, for some reflex troubles, by a physician in another city whom we do not recognize as "regular." I was interested because he claims to remove the uterus and control hemorrhage without the use of clamps or ligatures. While this may sometimes be possible, to get information from another source I wrote to a distinguished laparotomist in Chicago and inquired if it were true that this kind of work had been done there. He replied that he had never seen the work of this man, but that another distinguished gynæcologist had, and says that clamps or ligatures are used. If the uterus could be removed without the use of ligatures or clamps, it would be a beautiful operation. In the cases reported by this gentleman, hysterectomy was not indicated because they could be treated and cured by other less heroic means; and the uterus, ovaries and tubes should not be removed unless no other treatment will cure the patient.

DISCUSSION.

DR. J. M. MATHEWS: There is one point in the remarks made by Dr. Wathen which should receive more than passing notice; that is in reference to the gentleman who claims to do a hysterectomy without clamp or sutures. Two months ago I was in the office of a distinguished surgeon of Chicago, and he told me that a few weeks previously, two ladies had come into his office to see a neurologist (the two gentleman had their offices together) and when he (the neurologist) stepped up into the reception room, one of the ladies addressed him about as follows: "Doctor, I have come here to have you apply some electricity and before I engage you to do so, I should tell you that I have just had my womb removed, and my friend here also has had her wombed removed." This doctor was a gentleman of distinction and learning, and said: "Madam, you must be mistaken, you have not had your womb removed." In reply to this the lady remarked, "Well, Doctor, I suppose you can tell by making an examination; investigate for yourself and see if it is true." He told me that the Doctor made an examination and found of course that the womb had been removed, and upon questioning the two ladies he ascertained that it was not especially for any womb disease that they had the operation done, but for some reflex neurosis; that they had also, undergone the so-called new American operation, which is the resection of two inches of the lower rectum; that they had also had their urethras dilated and before the womb had been removed, the cervix had been dilated. This gentleman in commenting upon it to me remarked that it was no new thing; that the gentleman who removed the wombs of these two ladies had reported thirty cases at that time, where the womb had been removed for reflex disturbance, etc., etc.

Now, I say that it should receive more than a passing notice from the gynæcologists here in Louisville, for the reason that if this thing is true, it should receive the condemnation of all right-thinking men in the profession of America. That women should submit to having their wombs removed where there is no ocassion for it is an outrage, and certainly if this man's claim is not a true one, if he did remove the wombs in this manner, then that portion of his work should be exposed; and I surely think it deserves recognition enough from the gynæcolgists of this country to look into the work and find out if this thing is actually going on, if for nothing else than condemn it.

---

Dr. S. G. Dabney (visiting) read a paper on

ELECTRO-PUNCTURE FOR REDUCTION OF TONSILLAR HYPERTROPHY WITH CASES.

(See page 162)

DISCUSSION.

DR. WM. CHEATHAM: I used the electro-puncture sometime ago more than I use it now. The cases Dr. Dabney has spoken of are those in which we use the electro-puncture mostly. I think a great many of these cases may be relieved by punching out the tonsils. I have had made for this purpose a punch, and by pressure on the outside of the neck shoving the tonsil well in, I have been able to get the tonsil out by means of the punch. One serious objection to the use of electro-cautery is the pain that it produces. I object to the use of cocaine because we are much more liable to have secondary hemorrhage. I have found that usually tonsils can be removed either with a small tonsillitome (Mathieus) or with the punch.

As to hemorrhage from tonsils: I do not think it is so dangerous as a great many operators would have us to believe. Hemorrhage of a serious nature occurs so seldom in this situation that I do not think it need be feared. I have never seen a case of serious hemorrhage following tonsillotomy. I remember in one instance after removal of the tonsils from a child, there was a moderate hemorrhage which was easily controlled with tanno-gallic acid. With the instrument which I show you here, pressure can be applied, so I do not fear hemorrhage at all. It always seemed to me that there was always greater danger of sepsis following the use of the galvano-puncture than the knife on ac-

count of the slough that follows. Again there is a much more dense area of cicatrical tissue left after operations with the galvano-puncture than follows the use of the knife.

I have one of the instruments exhibited by Dr. Dabney in my office, and have used it occasionally in cases in which its use was indicated, and while it is the most perfect instrument of the kind yet invented, there are several objectionable features. The instrument for controlling the current is the best that I have ever seen, and the size of the instrument as a whole is in its favor as it can be conveniently carrried from place to place.

DR. J. M. RAY: The question of hypertrophy of the tonsil is an extensive one. The subject to which Dr. Dabney particularly referred is one that has interested me to a very great extent. I have used the galvano-cautery; I have one of these instruments and have used it in my office for a year. I find it the most reliable and most satisfactory form of galvano-cautery that I have ever seen. It has been my practice in the treatment of hypertrophied tonsil in the adult to use something else than excision. Wherever it is possible to effect removal of the tonsil by the galvano-cautery instrument of Wright, I think it will be found to work very nicely. I have employed it a number of times with satisfaction, and without any hemorrhage. I have also used the irido-platinum wire snare with success. I have frequently found fibrous tonsils not particularly enlarged, containing crypts filled with concretions giving rise to foul breath, and frequently the patient complains of attacks of dyspepsia and other reflex symptoms from the presence of these concretions in the tonsillar crypts. I very frequently have a great deal of satisfaction from the application of chloride of zinc in saturated solution after slitting up the opening into the crypt. I believe in this way marked atrophy of the tonsil may be accomplished. I frequently see tonsils buried behind the pillar of the fauces, containing a small quantity of cheesy matter, which is very foul and giving rise to very serious reflex troubles.

The last time the question of removal of the tonsils was discussed I stated that I had recently had some disagreeable results from removing the tonsils in an adult. I have had two or three cases where there was considerable hemorrhage. I must say that I am somewhat timid about excising such with the guillotine. My experience has led me to have very serious misgivings in this direction. While the galvano-cautery is of great service in the treatment of hypertrophy of the tonsils, it certainly makes the throat very sore for some time. I am very careful to find the opening in the crypt of the tonsils, and make my applications so as to get as nearly the bottom of the crypt as possible.

I never hesitate about removing the tonsil in a child under fifteen years of age, by the guillotine, passing the instrument well down, and cutting out all I possibly can. But in the adult I always feel somewhat uneasy about the after result.

As to the best method of controlling hemorrhage in this situation; A great many instruments have been suggested for pressure on the tonsil to stop the bleeding. I have found, however, that in a majority of these cases the throat is very sensitive, and any instrument passed into the throat is very hard to keep in position; even if the patient would tolerate it the contraction of the muscles of the pharynx would push it out of place. All instruments in my hands for this purpose have proven rather unsatisfactory. The best thing I have found for controlling hemorrhage in this locality has been my thumb. If the bleeding gets to a point where I am unable to stop it by local applications, such as tanno-gallic acid solution, or the packing of powdered tannic acid into the bleeding surfaces, I pass my thumb well in between the pillars of the fauces, and by keeping up the pressure for a few minutes, allowing the blood to clot in the vessels, I have always been able to stop the hemorrhage in this way.

DR. WM. CHEATHAM: I believe there is considerable danger of secondary hemorrhage after use of the galvano-cautery puncture, knife or snare; my objection to the snare especially, is the danger of secondary hemorrhage. If there is going to be any hemorrhage, I would rather use the guillotine and have the bleeding occur primarily. After use of the galvano-cautery a lough takes place, and there is danger of secondary hemorrhage six, eight, ten or many hours after the operation. We have no such danger to contend with following the knife.

DR. S. G. DABNEY: The discussion has taken a turn rather wider than the remarks I made called for. In deep-seated septic tonsils we must use something else than the knife, we cannot reach them with the tonsillotome, and my reason for showing the galvano-cautery was to demonstrate its use in this class of cases. Many of us have tried instruments more or less similar to the gouge and small guillotine shown by Dr. Cheatham. At a recent meeting of the Medico-Chirurgical Society I exhibited a small instrument made under my direction, and combining the advantages of the McKenzie and the Mathieu instruments. Still such instruments are not usually so satisfactory in these cases as the electro-cautery. One reason is that it is difficult to separate the tonsil from the pillar of the fauces with these cutting instruments.

As regards the danger of hemorrhage in removing large fibrous tonsils in the adult: I have done this operation with the guillotine

without troublesome hemorrhage with exception of one case, but like Dr. Ray I never remove a large tonsil in the adult without some uneasiness. Bosworth nearly always uses the cold wire snare in operating upon cases of this kind. As to instrumental means for controlling hemorrhage following tonsillotomy I believe the most successful is Clendennen's forceps. But in my experience this method has not only given rise to very great gagging on part of the patient, but actual vomiting has sometimes followed, so the effect would really seem to me to be to increase hemorrhage rather than arrest it. The tanno-gallic acid (6dr, tannin, 2dr. gallic acid to one oz. water) is a valuable means for arresting hemorrhage. Of course, in children the danger of hemorrhage is practically nil. So far as I am aware there has never been a serious case of hemorrhage following tonsillotomy in children. There have been a very few fatal results and quite a large number of serious and alarming ones after the same operation in adults. In the only case of serious hemorrhage I have had, already referred to, the McKenzie instrument was used on one tonsil and the Mathieu on the other. Though the tonsillitome was used the hemorrhage was secondary, coming on about six hours after operating and this is very often the case.

DR. J. M. RAY: In the variety of tonsils that Dr. Dabney has mentioned it has been my experience to find a great many of them attached to the pillar of the fauces, so that in removing them we are liable to cut the pillar of the fauces. In a number of cases I have followed the suggestion that I have noticed somewhere, of simply separating the attachment of the tonsil to the pillar of the fauces and the tonsil will then shrink.

---

### ABSCESS OF THE TONSIL.

DR. WM. CHEATHAM: A gentleman recently consulted me complaining of some trouble about the throat, that it was the source of constant irritation. He is an elocutionist and takes the best possible care of his throat. I examined the tonsil; it was a little hypertrophied, and there were quite a number of lacunæ leading down into the tonsil. The tonsil projected only slightly beyond the pillar of the fauces. By making gentle pressure I remove a small quantity of very thin creamy looking pus. He told me that this condition had existed for five years.

It is the first case of abscess of the tonsil existing for such a great length of time that I have ever seen. I treated the case by slitting it down to the bottom of the abscess, washing out thoroughly and making application of chromic acid. The patient has had no trouble since.

### MALIGNANT DISEASE OF THE RECTUM—OPERATION.

DR. W. O. ROBERTS: At the last meeting of this society I reported a case of malignant disease of the rectum, and brought the patient with view of having Dr. Mathews especially examine him, but as he was not present I did not exhibit the patient. He was a Polish Jew about forty-five years of age, who had been complaining of rectal disease for quite a long time, and when I examined him I found on the posterior surface of the lower end of the rectum, an indurated ulcerated surface about the size of a silver dime, and on either side of it was a hard nodule about as large as the end of your little finger. I resected about 1½ inches of the lower end of the rectum.

There is no doubt in my mind about the trouble being malignant in character, but no microscopical examination has been made as yet, of the specimen removed. The operation consisted in first splitting thro' the back part of the sphincter muscle and then dissecting the gut, pulling it down and stitching it to skin at the verge of the anus (Whitehead's operation). The nodule was located in the sub-mucous tissues and was quite hard.

### DISCUSSION.

DR. J. M. MATHEWS: The reason I suggested that Dr. Roberts' report the manner of resecting the growth was this: I am indebted in an especial way for the technique of Kraské's operation to Dr. H. O. Walker, of Detroit. At the meeting of the Mississippi Valley Medical Association at Indianapolis a few months ago, Dr. Walker reported two cases of Kraské's operation for the removal of malignant growths of the rectum, and suggested the use of Murphy's button procuring of course a very large size for the purpose, and stitching the gut above and below. He exhibited the button, but remarked that he himself had not yet used it.

In the last issue of the *American Medical Association Journal*, Dr. H. O. Marcy, of Boston, reports a case where he acted upon Dr. Walker's suggestion with a perfect result. I was impressed at the time of Dr. Walker's report that it was a most admirable suggestion, and asked him to try it on his next case and report it, that he might be on record as making this valuable suggestion in resecting the rectum. Although the credit is due Dr. Walker, his case was only incidentally referred to by Dr. Marcy in his paper.

In the case reported by Dr. Roberts, I believe that he pursued the only course, if he was satisfied that the nodule was malignant that he was dealing with. Inasmuch as the growth did not involve a larger space than he states, I believe the operation he did was quite sufficient. But it is suggested and practiced by those doing surgery upon the

rectum, that when the growth is at all extensive, or where there is disease taking in the entire circumference of the gut, or even anteriorly and posteriorly, or anteriorly and one side, that complete excision should be made. Now we are all very well aware of the fact that it is a difficult thing to do an excision and include a malignant growth in the manner Dr. Roberts suggests. I have done the same operation that Dr. Roberts did in this case, and with considerable success. I say success in that the man was able to control the passage of feces after I resected the lower end of the gut which included the sphincter muscles.

There is one point in Dr. Robert's report that I have had occasion to mention before. I know many authorities say that it is the proper thing after a division of the rectum to bring it down and attach it to the true skin. I have attempted to do this, and in several instances thought I had succeeded, but in each case the stitches separated, and I had trouble later from the granulating surfaces, and there was free discharge of pus. I suggested a number of years ago that where a resection, say of 1½ inches of the lower rectum is made, it is best to leave the gut without stitching and allow cicatrization to take place, the surface healing by granulation, inasmuch as the cicatrization itself would act as a wonderful aid in controlling the feces, especially if the sphincter muscle is removed in doing the operation.

Latterly I see most all the men who do work in this line believe in Kraske's operation for the cure of malignant growths of the rectum, especially if it is located at any height. And there is no doubt, that by removal of a portion of the sacrum and getting in from behind, we have an opportunity to handle the rectum in a manner that we cannot possibly do unless we do this operation suggested by Kraské, which is coming into vogue and is being used by the majority of men who are operating on the rectum. Of course Kraské's operation is thoroughly understood, and it is not necessary to describe it. One great thing in its favor is that the sphincter muscles are saved.

Dr. W. O. ROBERTS: In the operation of Kraské, the disease, as Dr. Mathews says, is situated high up in the rectum, and usually there is a point below that is considered in a healthy condition. I would like to ask Dr. Mathews whether he has done or seen done the operation of Levy. That is one in which a flap is made of the soft tissues and bone above, making a transverse incision through the lower part of the sacrum, then two vertical ones, turning it down—a trap-door flap, as it were—resecting the rectum and then replacing the flap. Levy reports a number of cases in which he has done this operation with good results and it seems very plausible.

CHRONIC ANÆMIA.

DR. P. F. BARBOUR: Last summer I was called to see a patient in the absence of her regular family physician. The patient was a lady of about thirty-two; she was pale, emaciated, very weak and lying in bed. She had no abnormal temperature then, and did not have during the course of her illness. The symptoms she complained of were palpitation of the heart, which was very violent, sufficient to shake the head of the bed and waking her at night, and belching a great deal of gas from her stomach. This eructation had no connection with any particular food except that potatoes seemed to make it worse. This symptom was always present and very annoying. In addition to this she complained of some rheumatic pains in the shoulders. She had been placed upon a milk diet—I have forgotten the amount per diem. and pepsin. She did not seem to be improving upon the milk diet, in fact she was becoming weaker all the time when I was called to see the case. I examined her very thoroughly, found the lungs normal, heart dilated and a basic murmur with the first sound. There was no tenderness about the stomach, no tumor and no dilatation. As far as physical signs go there seemed to be nothing abnormal about it; the bowels were always constipated. She said that after each action of the bowels she would have slight prolapsus of the anus. She complained of leucorrhœa, only, however, during these attacks, from which she was then suffering. In each attack she would be in bed for about a month. She was very nervous; pupils would dilate and contract while she was talking. The slightest light striking her eyes would produce a very marked effect upon the pupil.

I concluded that the milk diet treatment was not the proper one in this case. It seemed to me there was some trouble at the bottom of all these symptoms, that they were not due to any functional disturbance of the stomach, but that chronic anæmia might be responsible for her varied ills. We know that chronic rheumatism is a most frequent cause of anæmia, and this patient had been suffering with pains in the shoulders and muscles of the legs for a number of years. With this idea in view, I changed the treatment entirely. I put her upon six meals a day, of course giving a small amount of food at a time, but the most varied and nourishing food I could get her to take. I excluded nothing from her diet practically, excepting cabbage. Everything that could be easily digested was allowed her. In addition to this she took iron and cod liver oil. In less than four days she had gotten up out of bed, and in the course of the next month she gained twenty-five pounds.

# CURRENT LITERATURE REVIEWED.

IN CHARGE OF ELLISTON J. MORRIS, M. D.

THE MEDICAL CHRONICLE

of Manchester, Eng., for January contains a paper by Dr. W. Dowson on

**The Local Lesion of Scarlet Fever.**

The author contends that (1) The primary local lesion of ordinary scarlet fever is in the tonsil. (2) This disease is a local disease of these parts and associated lymphatic glands, the general symptoms being caused by the absorption of toxines produced by the microbic growth at the local lesion. (3) The incidence of the disease aud the subsequent immunity are related to the structure and life history of the tonsils.

The author has made over 500 observations and tabulates the results in the paper. He sums up as follows:—(1) tonsilitis is invariably present from the very first in scarlet fever; (2) it is the first sign apparent both to the patient and to observer; (3) it recurs in in relapses; (4) its severity is directly proportional to the severity of the other associated features of the disease; (5) this difference in severity of the throat affection and its relation to the other marks of the disease are recognized as affording a basis, to a great extent, for the clinical classification of the cases of this disease; (6) it is absent just in those cases where there is probability that the local infection takes place at an unusual situation, as in surgical and puerperal scarlet fever; (7) it leaves in the tonsil a permanent lesion, which can be observed long afterward; (8) people who have normal tonsils have not suffered from scarlet fever; (9) people who have gone through an attack of scarlet fever have not normal tonsils; (10) the immaturity of the tonsils at birth, their development in early childhood, the onset and establishment of puberty acting by way of the tonsils, and the atrophied condition of these organs after the age of thirty, control to an important extent the incidence of this disease.

He believes that although the truth of these propositions has by no means been rigidly proved, yet the weight of evidence is decidedly on their side; and that it is more philosophical to regard a lesion with such relations to the rest of the phenomena of a disease, as characterize the tonsillitis of scarlet fever, as a cause, than to make this consequent upon and merely symptomatic of a specific septicæmia or some other circumstance of the existence even of which no satisfactory evidence is to hand; that, in fine, as in diphtheria, the throat condition and cervical bubo of scarlet fever are the analogues of the chancre and inguinal bubo of syphilis, or of the intestinal ulcers and enlarged mesenteric glands of enteric fever.

Dr. Charles G. L. Skinner advocates

**The Use of Salol in Diarrhœa.**

During an epidemic of summer diarrhœa, of twenty-three cases treated with salol, only one—a child eight months old—proved fatal. In very few cases were more than three or four doses necessary, and rarely were more than one or two loose stools passed after taking the first. Ordinary catarrhal diarrhœa, due to errors of diet, diarrhœa of children, diarrhœa occuring in the course of some other disease, two or three doses seldom fail to arrest, whilst in the diarrhœa of tuberculosis it can generally be relied upon to give temporary relief. The author has had no experience with the drug in typhoid fever, but thinks it worthy of a trial in this disease and and also in cholera.

In all these varieties of diarrhœa, the good effects of salol are most probably due entirely to its direct antiseptic action on the bowel contents—destroying bacilli, controlling acid fermentation of food and the putrefaction processes. The sedative action of carbolic acid will also lessen the peristaltic movements, and so relieve pain. The dose of salol for an adult is 10 to 15 grains (best administered in a teaspoonful of gruel or barley water), which may be repeated every four or six hours; to a child a year old, 1 or 2 grains may be given. It is very rarely rejected by the stomach, and in the above doses does not produce unpleasant after effects.

It is, however, necessary to guard against the possibility of carbolic poisoning by not continuing the administration of the drug over too long a period, or giving too large or too frequent doses.

---

BRITISH JOURNAL OF DERMATOLOGY FOR JANUARY, 1894.

Dr. W. Allan Jamieson writes of

**Acne:**

Acne is, when fully developed, a pustular inflammation, having its seat about a sebaceous gland, either on the face, or the anterior and posterior aspects of the thorax. He does not include similar eruptions elsewhere. The small pustular syphilide is widely diffused, and accompanied by constitutional symptoms.

The cause of acne seems to be disturbed circulation in the skin, coincident generally with debility, and imperfect sexual development, or indigestion, and the abuse of tea or alcohol.

The treatment is general hygienic, usually the use of iron with salines, touching the individual pustules with one part of ichthyol to four of water, or liquid carbolic acid, instantly followed by flexible collodion

Expression of comedones, followed by hot water bathing, and the use at night of a lotion composed of sulphur, glycerine, spirits of camphor and lime water.

℞ Potassæ Sulphuratæ.....
Zinci Sulphatis.....(ää ℥j).
Glycerini.....(℥j).
Sp. Vini Rectificati.....(℥ij).
Aquæ q. s. ad.....(℥iv).

In the morning bathe in tepid water and dust with the following:

℞ Acidi Borici.....
Zinci oxidi..... (āā 5j)
Talci..... (5j)
Boli Armeniæ q. s.....

Occasionally a small subcutaneous abscess requires to be opened with a fine knife.

Dr. Louis Wickham, epitomising Prof. Fournier, says: The term

**Syphilis Maligna Precox**

is applied to tertiary lesions, usually of the skin or nervous system, occuring during the first year after infection.

The skin lesions are large numbers of disseminated, rapidly extending, deeply ulcerating sores, so characteristic as often to permit of an instantaneous diagnosis. Phagedænic tertiary lesions always are early. This early form is always rebellious to treatment, the lightning variety killing in a few weeks.

*Treatment:* Boracic acid baths to get rid of scales, pus, etc. Mercurial plaster on the superficial ulcers changed night and morning.

No potassium iodide is used, and, when there is much anæmia mercury is postponed, and a mixture of extract of cinchonæ, grammes 3 to 6; syrup of bitter orange peel, grammes 60 is used. Also iodo-tannic syrup, made as follows: Iodine, 2 grammes; soluble extract of rhatany, 8 grammes; syrup 1000 grammes; a teaspoonful night and morning. Milk is to be used freely, the urine to be watched, and when the improvement becomes marked, fresh pills of the proto-iodide of mercury with extract of opium are used.

The successful treatment of a case of angiokeratoma by puncture of each lesion with electro cautery needle is mentioned.

Success is also claimed for the treatment of obstinate eczema by poulticing, following this by a preparation of soft soap for twenty-four hours, or green soap, oil of cade and sulphur, equal parts, or salicylic or pyrogallic acid ointment to set up an irritation, which is then calmed down, to be excited again, and the process repeated as often as seems necessary. Sometimes mercurial plaster is applied over, but never beyond the inflamed area, to cause the irritation.

---

THE NEW YORK JOURNAL OF GYNÆCOLOGY AND OBSTETRICS

for January, contains an article on

**Vaginal Hysterectomy and its Limitations,**

by Alexander J. C. Skene.

The author, while favoring hysterectomy as a treatment af cancer of the uterus, does not believe that human life has been prolonged sufficiently to make one very enthusiastic over this mode of treatment; notwithstanding the favorable mortality of recent surgery. He recognizes a vast difference in the general condition of patients suffering from this disease. It is his belief that certain organizations have a deficient circulatory apparatus and are prone to degenerations of all kinds. In this class are included those in whom the pulmonary artery is undersized, a condition which has been found post-mortem in all cases observed who have died early in life from malignant disease of any part of the body. Further study may throw light on this diathetic condition. As between vaginal hysterectomy and other operations in the treatment of malignant disease. he thinks that hysterectomy is the most reliable treatment in certain conditions, but should only be classed with other recognized modes of treatment and not entirely replace them. The operation is indicated, in his opinion, when the disease occurs near or after the menopause; when it begins in the corporeal endometrium and a positive diagnoiss has been made; when the disease has not invaded the vagina or Fallopian tubes to any marked extent, and before necrosis has begun in any part of the normal tissue.

The starting point of malignant disease has an important bearing in the choice of operation. When it begins in the cavity of the body, vaginal hysterectomy is the only operation to consider. Vaginal hysterectomy is not contraindicated, but is less liable to be followed by a favorable result when necrosis has begun in the diseased tissues.

High amputation, curetting and cautery are safer in perhaps a majority of cases of malignant disease and will give as complete and perhaps as prolonged relief as vaginal hysterectomy.

Summing up his views on this subject he states that in certain cases of cancer of the uterus vaginal hysterectomy is by far the best treatment and gives the most perfect relief and longer life than any other method. In other cases it is a more dangerous operation by far and does not prolonged life in a greater degree.

Following is a report of three cases.

Dr. Hiram N. Vineberg contributes an article on

**Anterior Vagino Fixation of the Uterus for Backward Displacements; a new Operation.**

He points out that the idea originated with Sanger in 1888. He gives in detail the technique of the operation with a report of four cases and concludes as follows:

1. Vagino-fixation is a perfectly safe operation and not difficult to perform.

2. It fixes the uterus in a more normal position than the other operations in vogue for backward displacements.

3. If unsuccessful it is not followed by any untoward sequelæ.

5. It finds its indication (a) in uncomplicated mobile retroversions with symptoms, when a pessary for some reason or another can not be worn; (b) in backward displacements with moderate adhesions which can be easily broken up under narcosis; (c) in the same class of cases with more firm adhesions, but which admit of being distended by an prior course of pelvic massage; (d) in prolapse of the uterus of the first or second degree with corresponding prolapsus of the vaginal walls; (e) in retro displacements of the uterus complicated with diseased annexa not calling for a radical operation—meaning salpingo-oophoritis of a moderate degree.

It is contra-indicated (a) in complete prolapsus, (b) in congenital retro-displacements, with very dense adhesions, (c) in those cases

of retroflexion in which the fundus is very much enlarged, and the isthmus atrophied to such an extent, as to give the so-called Hegar's Sign in the non gravid uterus, (d) in those cases of retro-displacements complicated with diseased annexæ, to such a degree as to call for a total removal.

Dr. John B. Harris, reports fifty operations on the uterine cervix for laceration, and regards the operation as one of the most serviceable and satisfactory within the scope of the gynæcologist. For suture material he has used satisfactorily, wire, silkworm gut and catgut, but prefers silkworm gut. The treatment of the patient prior and subsequent to the operation as well as the mode of procedure in the operation is detailed.

Dr. H. G. Wetherill under the title of

**"Hysterectomy for Uterine Fibro-Myoma."**

makes some general observations on the necessity for removal of this class of tumors, and the great advance within five years in the surgery involved, and compares the results obtained by the three methods of operation: (a) method of extra peritoneal treatment of the stump (b) method of enucleation, (c) Baer's method. He concludes that methods (b) and (c) aretechnically perfect and attended with a minimum of shock, hemorrhage, pain and unpleasant sequllæ.

Dr. Arthur Bird in a brief article under the heading:

**"Alexander's Operation."**

enumerates some of the disadvantages of this procedure, as follows:

1. Shortening the round ligament does not relieve the condition causing the displacement. It is directed to the relief of a symptom and not to the cause.

2. It does not restore the uterus to its normal position or place in the pelvis. The obstructed circulation in the pelvis is not relieved, but on the contrary is often increased.

3. The shortened legaments again become stretched, or give away from their attachments allowing the uterus to fall back into its former retroverted position.

4. Great liability to hernia follows the operation.

# PERISCOPE.

IN CHARGE OF WILLIAM H. BRICKER, M. D., B. SC.

## THERAPEUTICS.

### Treatment of Wound of the Common Femoral Vein.

Niebergall (*Deutsche Zeitschr. f. Chir.*, Band 37, Hefte 3 and 6) objects to the practice of tying both the common femoral artery and its accompanying vein in cases of complete or partial division of the latter vessel. By applying ligatures to both artery and vein the blood pressure necessary for dilating the collateral veins is prevented. The cyanosis and œdema observed in the lower limb after ligature of the veins alone are the results of this blood pressure, and usually disappear in the course of a few hours, after the collateral venous circulation has become freely established. Gangrene did not occur in any one of 25 collected cases of ligature of the common femoral vein for wound of this vessel caused in the removal of large growths from the upper part of the thigh. Of 10 cases of ligature of this vein for non-surgical wound, gangrene was observed in only one, which occured long before the antiseptic era. On the other hand, the results of simultaneous ligature of both artery and vein have hitherto been very unfavorable, gangrene having resulted in 62.5 per cent. of the cases in which one or both vessels had been wounded during the removal of a tumor, and in 50 per cent. of the cases in which either the vein alone or both artery and vein had been opened by non-surgical injury. The prognosis in these latter instances, though very unfavorable, does not absolutely indicate primary amputation. The limb should not be removed until after the appearance of gangrene. The following are regarded as the causes of the frequent occurrence of gangrene from ligature of both artery and vein: local anæmia of the peripheral parts of the limb which are thus rendered liable to become necrosed; infiltration of blood in the soft parts and vascular sheaths, which hinders the flow of blood along the small arteries and its return by the collateral veins; as a consequence of the presence of blood clot in the tissues there is a tendency to the absorption of fibrin ferment through the walls of the veins, and to coagulation of the blood contained within these vessels. Compression of the vein, partially divided by antiseptic plugging is not likely to be of service except in cases of small external wound, and therefore is contraindicated when the vessel has been wounded during the removal of a large tumor. Lateral ligature or sutures of the injured vein is indicated in cases of small and longitudinal wounds through its wall. In instances of total or almost total division of the vein circular or complete ligature is always necessary. In cases in which the vein is so involved in a maliguant growth that its walls are infiltrated with morbid structures the affected portion of the vessel should be excised after the application of two or more ligatures.

### Pathology of Scarlet Fever.

Berge (*Union Med.*, December 30th, 1893) considers scarlet fever a local infection due to the streptococcus. These organisms are cultivated in the crypts of the tonsils, and there secrete a toxin, the diffusion of which throughout the organism produces the

cutaneous and mucous eruptions. Puerperal and traumatic scarlet fever results from local infection of the uterine surface, or various other mucous or cutaneous surfaces, by the streptococcus. These conclusions were based on the following facts: The scarlet fever eruption follows the affection of the tonsils; the extisence of scarlet fever with eruption in which the tonsillitis and its specific complications are the only affections; the constancy of the streptococcus in the tonsillitis of scarlet fever; the streptococcal nature of the complications of scarlet fever; the relation of scarlet fever to puerperal infection; and lastly, the ease with which the erythema-producing properties of the streptococcus can be demonstrated.

## MEDICINE.

### Transitory Aphasia in Pneumonia.

Chantemesse (*Bull. et. Mem. de la Soc. Med.*, December 22d, 1893) has observed more or less persistent aphasic phenomena in pneumonia, as in many infectious or toxic diseases. Some are due to structural lesions easily detectable—meningitis, softening, etc., while others cannot be ascribed to any such structural defects of the nerve centres. The latter class have a distinct clinical physiognomy, and usually occur at the end of the second or third day of the pneumonia. The aphasia is sudden in onset, but is often preceded by certain abnormal sensations in the head. Consciousness may not be lost, and the intellect may not be completely blunted; but at other times the attack is a regular apoplectiform one. The aphasia is identical in character with that which results from lesions of the third frontal convolution, and in the course of a few hours intelligence is sufficiently restored for the patient to indicate by gestures what he wishes to say. The lower part of the right side of the face is always paralysed, and the tongue deviates to the right; the right hemiplegia may be complete, but more often the paralysis is limited to the face, tongue, and the superior extremity. Sensibility and the tendon reflexes are usually little altered, but vasomotor phenomena, consisting in redness, œdema, and often elevation of the temperature of the paralysed limbs, may be present. The paralatic accidents do not appear to modify the course of the pneumonia, nor has their disappearance any prognostic value as regards the termination of the pneumonia. The duration of aphasia is short, sometimes four or five days or more. Sometimes twenty-four hours after the onset of complete aphasia speech is entirely recovered; the facial paralysis usually disappears with the aphasia, but complete hemiplegia, which is rare, is more persistent, and may be of several weeks' duration. Reasons for not considering the attacks hysterical are given, and they are contrasted with attacks of hysterical aphasia. In addition to other evidence against the structural nature of the lesion, a case is cited in which Berger found no changes in the brain of a patient with pneumonia who died five days after the onset of aphasia. Two hypotheses considered as possibly accounting for the attacks; one is that they are due to the direct action of toxic microbes on the nerve centres, and the other is that contraction of the Sylvian artery and its branches is induced, with consequent disturbance of the circulation in connection with the nerve centres which this artery supplies. The author inclines to the latter views as being the probable explanation of the phenomena.

### Idiopathic Hemorrhage of Septic Origin in Infants.

E. v. Dungern (*Centralbl. f. Bakt.*, October 28th, 1893) describes a case of this nature. He alludes to previous work upon this subject, which goes to show that idiopathic hemorrhage occurring in newborn children is frequently to be traced to bacterial influence. The organisms hitherto found are streptococcus pyogenes, B. pyocyaneus, and certain undescribed bacilli. The extravasation of blood has been explained on a theory of embolism. In the case now described, v. Dungern isolated an organism which produced hemorrhagic septicæmia in certain animals. The case was that of an infant without any family history of a nature to throw light upon the condition manifested. It died six days after birth, having exhibited the following symptoms—great emaciation, slight rise of temperature, scattered petechiæ, hemorrhage from one ear, and from the mouth, nose, and bowel. At the necropsy blood extravasations were found in accordance with the clinical symptoms, and there was also thrombosis of the umbilical arteries, the connective tissue about which was infiltrated with effused blood. In clot taken from these vessels there was found a bacillus with the following characteristics—length 1 to 2 m., breadth one-half the length; a well-marked capsule present; no movement seen; unstained by Gram; no spore formation; growth at the room temperature, in presence of oxygen, upon the ordinay media, with gas formation. The bacilli often occur in twos. They are pathogenic for mice, guinea-pigs, and rabbits. In animals of the last two classes, in which death followed rapidly upon subcutaneous injection of a broth culture of the bacillus, blood extravasations, some containing the organisms, were found scattered extensively about the various organs. Von Dungern is unable to decide whether the capsule bacillus now described is a viruleut form of the pneumobocillus (Friedlander) or a distinct organism. He regards it as the cause of the disease under consideration. The proximate cause of the blood extravasation is probably the damage done to the walls of the blood vessels by the toxic products of the bacillus.

### The Influence of Intra-Nasal Conditions Upon External Affections of the Nose.

Little literature is to be found on this subject. Crying produces a hyperæmia of the

Schneiderian membrane, also external redness and swelling of the nose. The same is true of hay fever and influenza. Strumous subjects with enlarged turbinated and thickened septa have thick ended noses. Conversely the narrow pinched nose of atrophic conditions is well marked. There are, however, many conditions in which the external or internal condition of the nose depend on a common cause, as acne and rosacea. The deductions are as follows:

1. Intrinsic nasal disorders are capable of exerting a decided influence upon certain conditions of that organ.

2. That in a few instances, at least, the external conditions depend largely, if not entirely, upon intrinsic influences.

3. That while in some cases the extrinsic condition may depend largely upon general causes not immediately associated with intrinsic exciting conditions, nevertheless the extraordinary activity of the nasal circulation, together with the existence of special nasal irritation may exert a decided influence upon the extrinsic condition of the nose.

4. In the latter case, while general treatment of the extrinsic condition must be mainly relied upon, relief of the internal condition by means of local treatment will naturally assist in affecting a cure.—D. Bryan Delavan in *American Medico-Surgical Bulletin.*

### Chloroform in Chronic Gastric Ulcer.

The treatment of chronic gastric ulcer has undergone no essential change during the last twenty years. It is the same as practiced and theoretically established by Von Ziemssen. However it is a well known fact that the customary treatment, owing to its long duration, is often impracticable. The author reverts to a method he has practiced a number of years. He endeavors to arrest by means of some antiseptic fluid the process of fermentation and decomposition in the stomach, avoiding all injurious action upon the ulcer, but at the same time aiming at the harmless stimulation of the torpid wound-surface. He employs chloroform water with Bismuth subnitrate in the following formulæ.

| | |
|---|---|
| Chloroform | 1 part |
| Water | 150 parts |
| Bismith Subnitrate | 1 part |

One-half teaspoonful every hour.

He declares that he has never observed any anodyne effect of the chloroform thus administered. The refreshing taste of the mixture most efficiently combats nausea and the severe thirst after hemorrhage; and any inclination toward further hemorrhage is overcome by the styptic properties of chloroform. The effect of this treatment is said to be striking, both in fresh ulcers and those of long standing. The sallow appearance of the patient disappears in a few days after treatment with chloroform and the malaise abates. The antiseptic action of the chloroform arrests the formation of septic substance during digestion; and its stimulant effect on the mucous membrane and ulcerated surface occasion a fresh formation of granulations resisting the absorption of septic substance, and brings about a cure within a few days, it is stated. The patients always experience a burning sensation at a certain spot over the stomach,—undoubtedly over the site of the ulcer, after taking the medicine, which no longer occurs however after 8-10 days.

In the author's cases, nutrition consisted at first of milk, or black tea with milk in equal proportions and toasted bread; at the end of the second week, of bouillon to which an egg was added later on; from the third week on, once or twice a day an additional egg, from the fourth week on easily digestible meat. A good red wine was allowed after the first week; constipation was treated with mild purgatives.—*Dr. Stepp. in Ther Monatsh.*

## SURGERY.

### Dawbarn (R. H. M.) on the Treatment of Sprains.

I divide sprains into three degrees, viz.: a mild sprain, a severe sprain, and a sprain of a still severer character. The treatment I would advise for a mild sprain would be the use of hot water and massage by means of vaseline. For a more severe degree of sprain I would apply the same treatment, plus Martin's rubber bandage, and urge the patient to walk about; and for the third degree of sprain I would use hot water as before, and a plaster-of-Paris splint, which would not be applied until twenty-four hours after the injury.—*Internat. Jour. of Surg.*

## OBSTETRICS.

### Cyst or "Hydrocele" of Nuck's Canal.

Fortin (*Rep. Univ. d'Obstet, et de Gynec.*, November, 1893) described a case of labial cyst not arising from the vulvo-vaginal glands. The patient was a married woman, aged twenty-six, strong and accustomed to bicycle riding. In April, 1892, she noticed a swelling in the right labium majus, not painful but inconvenient. It lay in the anterior part of the labium, and projected inwards. In diameter it measured four-fifths of an inch. It was irreducible, and, on account of its connections, it could not be entirely grasped between the finger and thumb. In April, 1892, shortly after its discovery, the cryst was punctured, glairy fluid escaped, and a 2½ per cent. solution of chloride of zinc was injected; no inflammation followed. In October, 1892, the cyst was tapped again, and creasote glycerine was injected. In January, 1893, it was dissected out. The detachment of its wall proved difficult. It extended above into the inguinal canal, ending in a cork-like pedicle. When removed it measured over two inches in length. No ligatures were required; there was much general oozing. Salol and absorbent gauze were used for dressing without drainage.

### A New Indication for Supravaginal Hysterectomy.

Under this title, Lauro (*Rif. Med.*, October 23rd and 24th, 1893), describes a case occurring in his own practice, and takes the opportunity of reviewing the indications for operative interference in displacements of the uterus. His conclusions are as follows: (1) In sexually active women, affected with retrodeviation of the uterus without any adhesions to the walls of the pelvis posteriorly, the intense sufferings in such cases can often be relieved by Dr. Alexander's operation, the severer operation of hysterectomy being thus unnecessary. (2) During reproductive life, in a woman afflicted with retroflexion or retroversion complicated by adhesions, the organ should be freed from its adhesions, and the round ligaments shortened intraperitoneally. This gives better results than ventrofixation of the organ. (3) In case of failure of these measures, recourse should be had to hysteropexy, by which means the organ can be more solidly fixed, without in general interfering with normal involution in future gestations. (4) Supposing laparotomy to have failed to prevent the return of the retrodeviation, and life to be in consequence a burden to the patient, one is then justified in suggesting exterpation of the reproductive organs. But this should never be done without a previous consultation. (5) In such cases the operation to be preferred is an abdominal hysterectomy so that adhesions contracted as a result perhaps of former operations, with the abdominal organs may be better dealt with. Such adhesions are often missed even by the most careful examiner before the operation. (6) If the menopause is past, there need be less hesitation in proceeding to hysterectomy. (7) The two operations, abdominal and vaginal hysterectomy, seem to differ but little on the score of danger to the patient, as in both cases the peritoneal sac has to be opened.

## ARMY AND NAVY.

U. S. MARINE HOSPITAL SERVICE FOR THE FIVE WEEKS ENDED JANUARY 20, 1894.

Bailhache, P. H., Surgeon; detailed by the President as Delegate to International Sanitary Conference Paris, France, January 15, 1894.

Sawtelle, H. W., Surgeon; detailed as Chairman Board for physicial examination of officer Revenue Marine Service, January, 19, 1894.

Austen, H. W., Surgeon; to represent the service at International Medical Congress, Rome, Italy, December 16, 1893.

Stoner, G. W., Surgeon; granted leave of absence for seven days, December 22, 1893.

Irwin Fairfax, Surgeon; to proceed to St. Petersburg, Russia, for duty December 28, 1893. To proceed to Paris, France, for temporary duty, January 16, 1894.

Carter, H. W., Surgeon; to report at Bureau for temporary duty, December 17, 1893.

Banks, C. E., P. A. Surgeon; detailed as Recorder Board for physicial examination of officer Revenue Marine Service, January 19, 1894.

Peckham, C. T., P. A. Surgeon; granted leave of absence for seven days, January 6, 1894. Granted leave of absence for six days, January 11, 1894.

Glennan, A. A., P. A. Surgeon; granted leave of absence for five days, December 20, 1893.

Brooks, S. D., P. A. Surgeon; to proceed to Sandusky, Ohio, as Inspector, January 17, 1894.

White, J. H., P. S. Surgeon; granted leave of absence for thirteen days, from December 18, 1893.

Caningron, P. M., P. A., Surgeon; granted leave of absence for thirteen days, from December 18, 1893.

Williams, L. L., P. A. Surgeon; granted leave of absence for fourteen days, January 17, 1894.

Bratton, W. D., P. A. Surgeon; to proceed to Wilmington, N. C., for duty, January 9, 1894.

Woodward, R. M., P. A. Surgeon; granted leave of absence for ten days, December 18, 1893. Granted leave of absence for fourteen days, January 17, 1894.

Stoner, J. B., P. A. Surgeon; to proceed to Marshfield, Oregon, as Inspector.

Gurterasly, M., P. A. Surgeon; to proceed to New Orleans, La., for duty.

Perry, J. C., P. A. Surgeon; to proceed to Norfolk, Va., for temporary duty.

Young, G. B., Ass't Surgeon; granted leave of absence for three days, January 1, 1894.

Brown, B. W., Ass't Surgeon; granted leave of absence for thirty days, December 16, 1893.

Rosenan, M. J., Ass't Surgeon; to proceed to Evansville, Ind., for temporary dury, January 13, 1894.

Gardner, C. H., Ass't Surgeon; to proceed to San Francisco Quarantine for temporary duty, December 22, 1893.

Nydegger, J. A., Ass't Surgeon; granted leave of absence for twenty-three days, December 20, 1893.

Oakley, J. H., Ass't Surgeon; granted leave of absence for twenty-five days, December 20, 1893.

Norman, Seaton, Ass't Surgeon; granted leave of absence for thirty days, January 15, 1894.

Prochazka, Emil, Ass't Surgeon; to proceed to Louisville, Ky., for duty, December 26, 1893.

## NEWS AND MISCELLANY.

The medical staff of the Methodist Episcopal Hospital has sustained a loss by the resignation of Dr. Frederick A. Packard, whose professional duties in other institutions have forced him to sever his connection with the hospital. The trustees will shortly fill the vacancy.

THE
MEDICAL AND SURGICAL
REPORTER.

No. 1928. PHILADELPHIA, FEBRUARY 10, 1894. Vol. LXX—No. 6

## ORIGINAL ARTICLES.

### A STUDY OF THE ILL EFFECTS OF TOBACCO ON THE THROAT AND NOSE.

WILLIAM T. CATHELL, M. D., Baltimore, Md.

Early in my professional career I attended Mr. McG., a stout, middle-aged man, who died from the abuse of tobacco in smoking and chewing. The history of this terrible case was briefly as follows: He was a brass-finisher by trade, and purposely taught himself to use tobacco, under the belief that it was a prophylactic against the harmful vapors unavoidably inhaled in that occupation. From the moderate use of tobacco, he gradually drifted into the slavish habit of chewing and smoking strong plug tobacco all the time, except for a period of about four minutes taken for breakfast, five and a quarter minutes for dinner, and three and a third for supper, even sitting up in bed several times every night to chew or to whiff his favorite short-stem clay pipe.

The result was that in the course of time a warty-looking pimple or growth formed under the tongue, just posterior to the sublingual glands, which gradually enlarged, ulcerated and formed a deep sulcus at the root of the tongue, which mass gradually enlarged and became more and more malignant, until every fibre and every papilla of the tongue became diseased and enlarged to such a degree that the horrid swollen mass protruded from the mouth, with its tip and anterior third fissured and angry.

The gums became red, scurvied, and unusually separated from the teeth, many of which loosened and fell out; his breath was loaded with fetor; the lumen of the throat was enroached upon; deglutition became more and more difficult, and was finally impossible, which caused a constant dripping of saliva, resembling ptyalism. The glands of the neck, both anterior and post-cervical on both sides, next became infiltrated and enlarged, but luckily did not ulcerate; after he could not swallow, his adipose tissue was completely absorbed, his muscles all wasted, and he became fearfully emaciated, with complexion bronzed, eyes sunk, and entire countenance hideously distorted; his blood was no longer fully oxygenated, his breathing became asthmatic, and, added to all else, he could speak with only a pitiful, inarticulate sound, and finally, after protracted, unappeasable torture, death came to his relief October 11th, 1886, in his fifty-fourth year.

Microscopic examination of a section of the sublingual mass revealed the fibrous stroma and the characteristic alveolar structure and the epithelial cells of cancer.

His death certificate should have been *Tabaci felo de se,* effected by impregnating the glands of the tongue, mouth and throat, by an almost continuous application of the juice and smoke of King James' "baneful weed."

Encountering this case so soon after the death of General Grant, in July, 1885, I directed my attention early in practice, to the harm that may flow from the abuse of tobacco, and since adopting a specialty that brings me into constant contact with

the throats and noses of smokers and chewers of every age and physical condition, I have continued in this enlarged field to note its effects on these parts, and while I fain would be neither a bigot nor a partisan in any tobacco controversy, I shall in this paper attempt to sum up the results of my study and experience.

Smoking and chewing, like malaria, alcohol, coffee, tight-lacing, late hours, high-heeled French shoes and other debatable agents, do not affect all alike, and some devotees suffer so little from their use and, within certain limits, even from their abuse, as to be practically exempt from harm.

I know a man whose pipe is seldom out of his mouth except when he is eating or sleeping; and another who lights one cigar by the stump of another all day except when he is eating, who, when he is where he cannot smoke, is chewing, and habitually sleeps with a quid in his mouth, without any appreciable injury; and each of you knows robust and healthy lovers of the weed, leading active out-door lives, who can smoke and chew any and every kind of tobacco, good or bad, with apparent impunity.

But, notwithstanding such exceptions, I am fully convinced that, as a rule, the majority of all who chew constantly or smoke more than two or three cigars, or pipefulls of tobacco a day, venture on dangerous ground.

For these reasons I would divide the patrons of tobacco into three classes: 1st. Those strong and healthy persons who can use it, and, within certain limits, abuse it too, without injury; 2nd. Those who can use it in moderation, with little or no discernable injury, but suffer if they abuse it; and 3rd. Those to whom tobacco is toxic, who must suffer if they attempt to use it in any way at all.

The last two classes fall within the scope of this paper, and I have seen so many distressed conditions of the upper air-passages created or made worse by it, that I have little hesitation in attributing the existence of a considerable proportion of important throat and nasal diseases that increase, or remain obstinate, to the use of tobacco by these two classes.

We all know that nicotine and the dark-brown empyreumatic oil produced in burning, are tobacco's two most harmful ingredients, and that to this oil is due the stale, pathognomonic smell of the old pipe and of the stale stump.

Nicotine is present in about two-and-a-half-per cent. in the mildest Havana tobacco, and ranges up to about seven-and-a-half per cent in the strongest Virginia.

Notwithstanding the fact that the properties of tobacco, chemical and physical, differ in chewing and in smoking, and also with the variety—and in smoking, also with the method—yet the pathological action of tobacco on the upper air passages is somewhat the same, no matter in what form its ingredients are brought in contact with them; but as a general rule, smoking is worse, because tobacco burning either in cigar, cigarette or pipe, not only imparts everything natural to tobacco, but also adds the oil and other products of combustion, and discharges them hot into the mouth and upper air passages; and the harder the burning weed in drawn in, the more deeply these go, and thus the hot smoke, impregnated with nicotine and the oil, comes in contact with every part of the throat and nose.

The smoker takes in less of the nicotine, but more of the oil, etc.; the chewer, little or no oil, but more of the nicotine; but, chewing and smoking involve spitting or swallowing the saliva, and both impregnate all the fluids that come into contact with the mucous linings, with tobacco. On the whole, however, I have seen chewing seriously affect as many persons as smoking; but were the mass of smokers to indulge that habit as constantly as the mass of chewers do, its ill-effects on the smoker's air-passages would be much more frequently seen, and we would much oftener find the mucous membranes of the patrons of the cigar, cigarette and pipe, in a thoroughly diseased condition, because these not only keep large quantities of the harmful constituents in continuous contact with the delicate mucous linings of the parts, but also because inferior grades of strong tobacco may be, and are, used in preparing smoking tobacco; and the burning of certain salts of potassium existing in it, and the heavy heated smoke, are all added to its own irritating power.

In chewing, one escapes the empyreumatic oil produced in burning, which would always be terribly toxic to the mouth and upper air-passages were it not for the fact that while smoking there is

an abnormal secretion continually taking place from the relaxed mucous membranes which, although it makes a good vehicle for conveying the nicotine, yet prevents more than a fraction of it from being absorbed by these membranes, the balance being either expectorated or swallowed; and we all know that spitting is a waste, and swallowing these tobacco-tinctured secretions, either to prevent this waste of saliva or because there is no convenient place to spit, is very harmful to the whole economy.

Of course, the one who both smokes and chews risks all the dangers that tobacco can present.

Whether the pipe, cigar or cigarette instils most oil and nicotine, and which is safest to smoke, are also questions of importance. Short pipes, and thick dumpy cigars are most apt to induce cancers, etc., and no habitual smoker should smoke his cigar down to the very end but should throw the last third away, as analysis has shown that the arrested nicotine, nicotianin and empyreumatic oil are there, all thickly accumulated. Using pipes with long stems, and smoking all cigars and cigarettes through smokers, enables the wise to escape much of the poison and heat, and robs smoking of half its harmful powers; and the later in the day one smokes or chews, the less it injures, and the earlier in the morning the smoke or chew is taken, the more it inhibits nerve power and nutritive activity; and, further, no one should shut himself up in a small room at any time, to smoke and create around himself a cloud of nicotine, for an increased amount of poison is then condensed on the delicate mucous membrane of the whole respiratory tract, and is thence taken into the entire system.

Cigarette smoking makes a delicate person's lips and face lose their natural healthy hue quicker than any other mode of using tobacco.

Tobacco is a potent agent that certainly is capable of creating a cachexy that interferes with both growth and repair, and I find that all inflammatory affections and lesions of the throat and nose, and especially those of specific origin, are more persistent and recover more slowly in persons suffering with what I might call scurvy; and not only the specialist, but also the general practitioner, knows how difficult it is to heal lesions, whether specific or benign, in the mouths, throats, or noses of those who either chew or smoke excessively, or rub snuff; and a scratch, pimple, blister or wart, or a sore lip, mouth, tongue, or throat, may be made cancerous by keeping it bathed in tobacco juice or smoke, especially, if the person is suffering with chronic tobacco intoxication of his system. In fact, it is scarcely possible to heal a sore or ulcer in the mouth, throat, or nose of one who persists in chewing or smoking.

For the same reason, no one with decayed or broken teeth, or dental plates that rub the gums or cut the tongue or mouth, should either smoke or chew, for either of these may be the fatal starting point. I have the records of five cases of epithelial cancer of the lips and tongue, four of which occurred in great smokers. Mrs. General U. S. Grant told me, in 1886, that General Grant's fatal case of throat disease began by his abrading a spot in the pharynx with the rough skin of a peach he was eating, and I have but little doubt that constantly bathing this abraded surface with tobacco smoke and tobacco-laden saliva, while his blood was already drenched and saturated with tobacco poison, did its fatal work for him.

Further, tobacco certainly acts as a depressant to feeble people and lowers their stamina; and such persons with a cancerous diathesis, or a syphilitic taint, or a scrofulous constitution, should not use it in any form, for in all such subjects the delicate pulpy tissue of the mouth, throat and nose, is very prone to inflammatory action, and also to ulceration from smoking or chewing, and in a large proportion of cases these degenerate into or light up the affection their predisposition or constitution indicates; and, in my opinion, no one who is aware that he has inherited a diseased or weak constitution, or defective vitality, should risk reducing his stamina further, by the use of this agent; and science, in the form of physiology and chemistry teaches, and my experience confirms, that if such an one uses tobacco while growing and maturing, he will not only have a weaker body and a weaker brain, but he will also be much more liable to catarrhal ailments of the upper air-passages; and I am quite sure that all throat and nose specialists will agree that tobacco has a softening and relaxing influence on the mucous membranes of the

mouth, throat and nose, in many who attempt its use, and induces catarrhal and other affections, and that it is unwise for certain varieties of defective people to risk its bad effects.

Neither can persons suffering from any form of neurasthenia smoke or chew without injury, and yet these are the very persons who oftenest have the *furore tabaci;* some smoking innumerable cigarettes, or lighting one cigar after another until they smoke six, eight, or a dozen a day.

Smoking also creates in some persons a persistent, hacking cough, due to tenacious mucus that accumulates in the pharynx and larynx, dependent on a morbid, infiltrated condition of the tissues of the palate and throat, which often degenerates into a condition that closely resembles clergyman's sore-throat, or into diseased throat and post-nasal catarrh combined. I make an emphatic interdiction of tobacco in all such cases.

I am also convinced that in some people there exists a close sympathy between the olfactories and the nerves of the mouth, and that in some the frontal sinuses are also invaded after tobacco excesses, as gravedo and frontal headache often attest.

Besides the classes I have spoken of, whoever else finds that tobacco is injuring him should stop its use; but, unfortunately, many of those it is affecting never realize that it is doing them any harm, attributing all their ailments to other causes.

When tobacco induces a sense of tumefaction, heat and pricking in the throat, it should be let alone; and those whom it occasionally makes sick, and persons with a poor appetite, and those recovering from wasting sickness, are among the ones it injures most.

The habit of swallowing tobacco smoke and then expelling it through the nose, and also of coughing it into the lungs, are both very injurious, as they irritate and dry the mucous membrane of the pharynx, larynx and trachea, and subject them to the various tobacco affections. Blowing it through the nose is also harmful, as it is a fruitful cause of the hypertrophic thickening of its mucous membrane, so often discovered in smokers, and the sense of smell is also greatly impaired by smoke-blowing.

I would not be understood to say that tobacco induces these affections only, but it is chiefly with them that I come in contact.

With feminine smokers and chewers I have had no experience, and with snuff-pinchers and snuff-rubbers but little; but I have encountered two cases of nasal polypi in females due to the use of snuff, which is less astonishing when we remember that all tobacco dust has a notoriously irritating affinity for the Schneiderian mucous membrane.

There is in my mind a strong suspicion that the high degree of injury that follows cigarette smoking is not due solely to the tobacco they contain, but is also due in part to its union with the so-called rice-paper wrappers in combustion; and I would here emphasize that in all smoking, and in chewing, too, much depends on the quality of the tobacco.

I can usually distinguish the oral cavity of the person who carries smoking to excess by the dusky red, velvety, or hyperæmic appearance of the lining of the mouth, throat and nose, and by the throat becoming irritable and hoarse upon every effort in speaking and singing.

Tobacco cautiously used is certainly a charming pleasure in ripe manhood, and a solace in old age, and is rather beneficial than otherwise to thousands of healthy but careworn and toilworn people, and also to tens of thousands of soldiers, sailors and other idle people on whose hands time hangs heavily; and were one to ask me how to get the good out of it without risking the bad, I should advise him, among other things, to avoid smoking another's pipe, for fear of contracting disease,—the largest indurated specific sore I ever saw was on a colored man's lower lip, contracted from another's pipe; also, never to even smoke his own after it had become blackened and oil-soaked, and also never to light a stale stump, or habitually smoke a short stem-pipe.

A cigar-smoker, or a cigarette-holder, or a new or freshly burned clay pipe, in point of safety and cleanliness, is far superior to putting mouth-to-weed in smoking, and one's whole mouth and throat should be thoroughly cleansed with water after every smoke.

Neither striplings with unformed constitutions nor weakly growing youths should venture to either smoke or chew, because in youth the vital centres are all unripe and delicate, and the mucous

membranes are then marvelously hypersensitive to the effects of smoking and chewing; and if a growing boy's or an undeveloped puny youth's mucous membranes absorb either nicotine or the empyreumatic oil of tobacco, it poisons his springs of life and stunts his development mentally, morally and physically; and if he expectorates these poisons, then the loss of saliva lessens the growth and repair of his delicate and easily injured vital centres, and I am positive I have seen more than one unripe devotee stunted in body and mind, and I could at this moment name half a dozen young men and boys who are injuring their throats and noses with cigarettes, who will later in life have granular or follicular pharyngitis, somewhat akin to clergymen's sore-throat, with an annoying discharge of mucus from the posterior nares into the throat, with relaxed tickling uvula, which may hang on for years, and neither get well nor kill, but be an annoyance to himself and to every one around. I know a feeble, narrowed-shouldered young man, who is at this moment cigaretting himself to either the invalid's couch or the grave, through his delicate mucous membranes; and we, as hygienists, can do the weakly ones of the rising generation no greater service than to point out tobacco's injurious effects on their throats, upper air-passages, etc. I have observed but few youths whose sensitive mucous linings could endure tobacco's toxic influence without showing symptoms of weakness, morbidity and disease; and were I to recast our pharmacopœia I would not only call hyoscyamus hensbane, aconitum wolfsbane, and arsenic ratsbane, but would be strongly tempted to give tobacco the synonym of youthsbane.

If anyone considers this indictment overdrawn, let him stand at Broadway and Baltimore Street, or at Charles and Preston, or at any other spot where he can see a constant stream of passing men, boys and youths, and carefully scan all the immature and sickly devotees who pass with cigar, pipe, cigarette or quid in mouth, and he will soon detect written on many of their faces and figures, the unmistakable signs of tobacco cachexy, some with pale, sharp, wizened visage, round shoulders, shuffling walk and anxious, nervous, tell-tale addresses; others with complexions stained an ugly green or a dirty yellow or a dusky bronze color, as if their blood were turned to a greenish or yellowish fluid instead of the natural red.

The mouth, throat, and nose of a healthy person have a clean smooth, pale, pinkish or lilac hue. Examine these tobacco mouths, throats and noses, and you will find every part unclean and ugly; probably a mouthful of saliva, as offensive as a bar-room spit-box, that must be either expectorated or swallowed before you can begin to examine; tongue furred, teeth incrusted with a dirty, scurvy-like, greenish deposit; the buccal surface of the cheeks either in a state of active or sluggish congestion; gums, palatine arches, velum palati, pharynx, epiglottis, larynx, Schneiderian membrane, and all the other soft tissues turgid and injected, or velvety, granular, purple with hyperæmia, and streaked with mucus, instead of being a clean natural red.

You will find, however, in this flaccid throng, that all have one set of muscles that are firm and strongly developed, i. e., the muscles of the mouth and lips; made so by the local exercise of grasping the cigar, pipe or cigarette, with jaws, lips and teeth, together with the constant gymnastic motions of chewing and spitting.

Some of this tobacco throng will present cases of ozena; others, catarrh of the throat and nasal passages, buccal inflammation, epiglottitis, relaxed and tickling uvula, chronic tonsillitis, laryngitis, trachitis, hoarseness or nasal twang in talking, due to thickening within the larynx, loss or impairment of smell, rotten breath, etc., which can easily be interpreted by the experienced; and I risk nothing in asserting that five-per-cent of all constant smokers and ten-per-cent. of all constant chewers, and twenty-five per cent. of all who constantly do both, are affected with one or another of these affections, and not thirty-per cent. of immature and sickly smokers' throats and noses will be found in a perfectly normal condition.

I do not think any one can safely use tobacco in any form in boyhood or early youth, and I am sure that smoking before the eighteenth year, and chewing before the nineteenth year, cut off from many a youth half his stamina and lessen all his natural talents and attributes; and I ask you to-day, as anatomists and physiologists, to think of a frail boy, or a callow youth,

who secretes and then ejects half a pint, or a pint of tobacco tinctured saliva daily, while both he and his friends are wondering why he is below par. You know and I know that it is as unnatural and harmful to him, to keep his sensitive absorbents and lacteals bathed in tobacco-tinctured, tissue-altering saliva, either by smoking or chewing, as it would be for a fifteen month's old colt to carry heavy weights on his back; and the delicately constituted youth, who learns to "chaw" because others do, or to show his rough side, or tries to blow as big a cloud of smoke as the other fellow does, is injuring himself mentally, morally, and physically, and although he may not realize it now, yet the day is not far distant when he will know it, and know it with regret.

In conclusion, I believe the majority of those who arraign tobacco, from King James in 1641, down to the Cranks of to-day, draw their indictments entirely too heavy. Personally, I have little or no prejudice against the proper use of the weed, either in smoking or chewing. Nor would I dare to say that every votary of tobacco is injured, or is on the road to ruin. Life is short, and every one should get all the rational, harmless enjoyment out of it he can; and while I am perfectly willing to agree that some can use either mild or strong, good or bad tobacco, very freely and experience no ill effects, I am also quite positive that it is highly injurious to the upper air-passages of all youths, and also to numerous adults, and that to some of these the free use of even the mildest and best tobacco is almost akin to suicide; and I think that we as physicians should counsel all growing youths to shun it entirely, and every adult with defective stamina, or a tendency towards any organic disease, or a bias for any cachexy, or an inclination towards any affection of the throat or nose, either to let it alone forever, or to determinedly limit its use to a harmless quantity.

# COMMUNICATIONS.

## SOME EXPERIMENTS WITH SOMATOSE—A NEW FOOD PRODUCT.

E. H. BARTLEY, M. D.,* Brooklyn, N. Y.

This preparation is claimed to consist almost entirely of pure albumoses. It is prepared from meat, and is a light yellow powder without marked odor or taste. It is hydroscopic and dissolves completely in hot and cold water. The solution has a faint alkaline reaction, and part of the substance is precipitated by careful neutralization, from which we conclude that there is present a small amount of alkali-albumin. Most of the nitrogenous matter is in the form of albumoses, there being only about 5 per cent. of peptone present.

For practical purposes we may regard the new food-product as a highly nutritious preparation of meat, composed chiefly of albumoses, with a small amount of peptones. Prof. Chittenden has recently published an analysis of Somatose, giving the following as its composition:

| | |
|---|---|
| Water | 8.94 per cent. |
| Solids | 91.06 " " |
| Mineral Matters | 6.95 " " |
| Total Nitrogen | 13.90 " " |

Matters insoluble in—

| | |
|---|---|
| 80 per cent. Alcohol | 80.91 per cent. |
| Albumose | 70.07 " " |
| Gelatose and Gelatin Peptone | 8.03 " " |
| Peptone | 5.01 " " |

From this exhibition of its composition, and from the well known results of physiological and clinical tests with peptones, we might expect good results from the use of somatose.

Gerlach, Politzer, and others have shown that *fully digested* meat preparations cannot be used long without producing diarrhœa and other digestive disturbances. My own experience has shown that after a few days patients develop a disgust for such preparations and decline to take them. The stomach becomes sick, the breath offensive, and they do not thrive well without other food. The greater the propor-

* Professor of Chemistry and Toxicology in the Long Island College Hospital.

tion of peptone in these preparations the less desirable, clinically, are they. This fact has become well known in the peptonizing of milk for infants. They will not thrive on completely peptonized milk, even when they can be induced to take it, and hence, no one now thinks of thoroughly peptonizing milk for infants or invalids. The same is true of the cereals. They agree when partially digested. It is for these reasons that this new preparation has been put upon the market.

The clinical use of this food upon a variety of cases have borne out the expectation derived from its chemical composition.

The cases on which I have tried somatose, included two cases of carcinoma of the stomach, one of phthisis, one of gastric ulcer with dilatation, two of choleraic diarrhœa in infants, with marked collapse, and one of gastro-enteric catarrh (summer diarrhœa).

In all cases the food was well borne and was retained when all other food was rejected. It was noticeable that in several of the cases, where there was complete anorexia, the appetite returned after from one to three days, and then the patients were able to retain and digest other food, rendering the further use of somatose unnecessary. In no case did it produce nausea or diarrhœa. The case of phthisis pulmonalis, above mentioned, was suffering with troublesome diarrhœa, with occasional vomiting at the time of beginning the use of somatose, but there was no evidence of an aggravation of the diarrhœa. The nutritive value of the food could be plainly seen in its effect upon the digestion and blood tension.

The effect upon the heart seemed to be more permanent than that of a stimulant, and I could but regard it as the result of a true nutrient action upon the heart muscle. I would explain its effect upon the digestive organs in the same way, *i. e.*, by its furnishing nourishment to the mucous membrane of the stomach, as well as to the increased general nutrition.

From the limited experience had with it, I do not regard it as suitable for long continued use, but it is especially useful in an emergency, when the digestive organs have failed to appropriate ordinary food, and for this purpose, it has seemed to meet the indications more fully than any of the commercial peptones, or so-called peptones, tried by me. In three of the adult cases, I compared the effect of somatose with that of some of these peptones, and in each case with marked credit to this preparation.

The trial with infants was confined to two cases of typical cholera infantum, and one of summer diarrhœa, of mild type. All covered.

The first case was a second attack in the same child during the season. This attack was accompanied by convulsions, followed by alarming collapse, high internal temperature and incessant vomiting. The food was begun at about nine in the evening. A half teaspoonful was dissolved in a wine-glass of water and a teaspoonful of this mixture given every half hour during the night. The effect was very gratifying. The restlessness, the rolling of the head from side to side and throwing the arms about had ceased by morning, and natural sleep followed.

The child was then given a mixture of equal parts of milk and water with a half teaspoonful of somatose dissolved in four ounces of the mixture. This was retained and continued for two or three days, when the usual food was resumed. If any part of the treatment of this child saved its life I should give the principle credit to the food.

The second case was less severe, but the result was a rapid recovery. The third case did not return after beginning the food, and I can only say that it recovered without further attention. The one thing that impressed me in both of the above cases of choleraic diarrhœa, was the rapid restoration of the digestive functions, after such a profound disturbance. I have tried to avoid enthusiastic praise of the results obtained in these few cases. So far as they go, they seem to show that we have in somatose a valuable nutriment in cases of great exhaustion and in digestive failure. It deserves a more extended trial.

# FIBROUS BODIES IN THE TUNICA VAGINALIS TESTIS; WITH A REPORT OF THREE CASES.*

THOMAS S. K. MORTON, M. D.†

I have thought it well to make these remarks upon the subject of fibrous bodies in the tunica vaginalis of the testicle, not only because of the inherent interest of their presence in that locality, but especially to emphasize their significance in determining the method by which the usually coexistent hydrocele shall be treated.

Many excellent text-books ignore the possibility of these bodies existing as a cause or complication of hydrocele, yet three cases have occurred in my practice within two years, and a search of the literature has demonstrated that they are by no means very rare. They may exist singly or in numbers; attached to the tunic or lying loose in the hydrocele sac. In size they vary from a pin-head to half an inch in diameter, although but one case is upon record of the latter dimension. The usual weight is from a fraction of a grain to five grains. In shape these bodies are generally smooth and polished like small beans, but may have become irregular by aggregation of two or more separate formations. A little pit or cup-shaped depression, when existing upon one side, is supposed to represent the vestige of a former pedicular attachment. Le Groux has recorded an instance where the body was cubical. In color they vary from white to dark yellow or red. In consistency, when fresh, they are usually firm and elastic, much resembling fibro-cartilage. When dry they become very hard and stony. These bodies have often been mistaken for bone because of calcification having taken place; in fact, this is a frequent degeneration. Yet some have unquestionably been proved to contain true bone. Usually but one body is found, but as many as five have been discovered in a single hydrocele.

There is reason to believe that loose bodies in the tunic almost invariably take origin from the walls of the sac, and particularly from those portions of the wall which invest the testicular surface. I have found reference to no case in which other origin has been proved. But, of course, the possibility of inflammatory bodies being formed in other portions of the tunic and being subsequently obtruded into the cavity must be acknowledged, as also must be granted the possibility of blood being effused and afterward becoming agglutinated into a fibrous or calcareous free body. It is likewise a possibility that the fluid of a cyst of the tunica vaginalis might precipitate certain of its contents and thus form the nucleus of a foreign body.

Too many observations are upon record to doubt that very many fibrous bodies take origin from the Müllerian duct and its extremity, hydatid of Morgagni, and from that portion of the tunic in the neighborhood of the junction of the testicle and epididymis. They may be found in the layers of or beneath the tunics or be attached thereto by a pedicle of varying length and breadth. Reclus observes that they may very rarely be hidden in a pocket in the tunica vaginalis with a small opening communicating with the sac cavity—from whence they may be shot out by pinching if not attached by a pedicle. Encysted blood-clots (see Case II.) may likewise exist in the tunic, but have no opening into the main hydrocele sac.

Usually the bodies under consideration are found in small hydroceles, but rarely in large collections of fluid. It is presumable that many hydroceles are directly caused by the irritating presence of the bodies. Loose and pediculated bodies have also been found where there was no accompanying fluid. They are unknown in early life and are very rare before puberty.

The fluid of small hydroceles containing bodies is apt to be of a yellowish or brownish color and viscid consistency, and even a bloody effusion may be present. Signs of recurrent or chronic inflammation, such as thick walls, fibrous bands passing between various portions of the interior of the sac, and perhaps multi-

* Read before the Philadelphia County Medical Society, January 10, 1894.

† Professor of Surgery in the Philadelphia Polyclinic; Surgeon to the Out-Patient Department of the Pennsylvania Hospital; Assistant Surgeon to the Orthopedic Hospital.

loculation due to fibrous inflammatory webs closing off portions of the vaginal wall, are often found to coexist with these peculiar bodies, especially where tapping or attempts at radical cure by irritant injections has been previously resorted to.

Upon section the bodies are generally found composed of concentric fibrous layers. These layers may be separated by colored lines due to deposit of blood pigment. The centre has occasionally a solid fibrous or calcareous nucleus; again, it may contain fluid or simply a dry cavity. The fluid, when present, may originate from the cystic interior of an hydatid of Morgagni or be derived from a blood-clot. Bodies have also been found completely calcified. It is possible for them to originate as true dermoid cysts or to have elements of such inclusive remains for a nucleus. Thus Lange has reported a case in which he found two long hairs growing from a hydrocele sac, and others have recorded true dermoid cysts as well as free portions of true bone and cartilage in connection with hydroceles.

The ultimate derivation of these bodies, which for want of a better name have been termed "loose," "fibrous," or "strange," is of great interest and has received much thought from the time of Morgagni, who first observed, described, and named them, down to the present. The Cohnheim theory of inclusion of fœtal tissues is at present the most widely accepted theory of the origin of the true "loose" bodies. Other varieties of bodies result from inflammatory deposits in the layers of the sac; almost always in the neighborhood of the globus major. These undergo fibrous and perhaps calcareous degeneration, become pediculated, and ultimately float free in the hydrocele upon rupture of the pedicle. Another method of origin is the formation of fibrous projections from the tunica vaginalis in the form of small papillomata of the endothelium, which later may become pediculated and subsequently free. This is the multiple variety, of which great numbers may be present. Blood-clot and other direct precipitations may, as has been said, originate another variety of the bodies. There are many instances recorded where the tunics or underlying tissues have become infiltrated through inflammation, senility, etc., with fibrous or calcific plaques. This variety alone may contain bloodvessels. Here pediculation or desquamation into the hydrocele sac rarely takes place, especially if the albuginea is involved. Sir Joseph Fayer speaks of this variety as of not infrequent occurrence in India, where hydroceles are prone to have very thick walls.

The symptoms indicating the presence of bodies in a hydrocele are vague and uncertain. But when a small cyst is present, giving rise to a sense of heaviness and originating unusual pain, and, moreover, if the walls are thick, or failure to cure by irritant injection has taken place, or if great pain or inflammation has followed tapping, the presence of bodies may be suspected. Free bodies might be observed by the light test, but owing to the usual position of attachment to the testicle it will generally fail. A careful study of the cyst by means of the recently devised electric hydrocele illuminator of Otis would certainly facilitate the search if the walls were translucent and the fluid clear.

Granting the presence of one or more bodies, it is probable, if not positive, that nothing short of incision of the sac and their removal will prevent recurrence of the hydrocele. My strong individual preference, as elsewhere stated at length,[1] in the treatment of such hydroceles is to split the sac to its full length, remove the bodies, curette any additional cysts, suture the edges of the sac to the edges of the wound margins, and pack with iodoform gauze until healing by ganulation takes place.

Case I. An Italian, aged thirty-seven years, was brought to me at the Polyclinic Hospital by Dr. J. M. Malatesta He stated that he had had a swelling of the left testicle for several years, and that it had been twice operated upon in Italy—whether it had been injected he did not know. Pain and a sense of weight were marked features of the case. No light could be seen through the swelling.

In view of the previous failures, the painfulness of the tumor and its failure to transmit light, I determined to incise the cyst and investigate. An incision to the whole length of the sac was made and its walls found to be very tough and thick. the contents presented the usual appear-

1 Philadelphia Polyclinic, September, 1892.

ance of hydrocele fluid. The sac was then inverted by turning the testicle out and the latter organ found to be attached to the base of the tunica vaginalis by firm adhesions which were honeycombed by a great number of subsidiary cysts varying from the size of a shot to that of a large pea. These small cysts were grouped mostly about the globus minor and body of the epididymis, but appeared to have no communication therewith. There were also found on the lower portion of the visceral layer of the tunica vaginalis in the same neighborhood several small calcareous tumors, the largest weighing two grains and well pediculated—about half a dozen in all. They sprang directly from the tunic, and the largest could easily have been broken from its pedicle and become a loose body in the cyst.

The small cysts were all split and curretted out, the foreign bodies removed by scraping, the sac edges sutured to the wound margins, the cavity of the tunica vaginalis stuffed lightly with a strip of iodoform gauze, and an antiseptic dressing applied over all. On the second day the packing was removed, the cavity washed out with peroxide of hydrogen first and with 1:2000 bichloride of mercury solution afterward and the packing replaced. This was repeated every second day until ten days had elapsed, when the cavity had become obliterated by granulations. The wound edges now rapidly cicatrized and approximated. At each subsequent dressing the line of granulations marking the wound were touched with stick nitrate of silver until complete healing was secured. On the fourteenth day he resumed his occupation, and on the twenty-fourth day after operation the last granulation had closed over.

This case illustrates bodies of inflammatory origin.

Case II. German, aged fifty years. Small hydrocele that had existed some years. Pain and weight were prominent symptoms. Transmitted light. Upon incision several cyst-like, somewhat pediculated growths from the tunica vaginalis in the neighborhood of the globus major on the testicular surface were observed. These were in turn cut off by dividing the pedicle with scissors. Free hemorrhage of venous character took place from the pedicles, but ceased as soon as the usual iodoform-gauze packing was inserted. The case promptly recovered and was afterward free of his former painful sensations. The growths proved to be blood-clots undergoing fibrous changes encapsulated by layers of the tunica vaginalis.

Case III. A Russian, aged thirty-eight years. Hydrocele of one year's duration. Much pain, uneasiness, and sense of weight in scrotum. Thinking it a rupture, he has been wearing a truss for some months. Tumor quite small and transmits light freely. Upon making the usual incision a free fibrous body two lines by three lines in diameter, of flattened globular shape, was discovered at the base of the sac. Fluid was straw-colored and amounted to about three ounces. The lining membranes were apparently healthy. Spasm of the dartos in this case prevented immediate packing with iodoform gauze and caused obtrusion of the testicle. This necessitated temporary suturing of the wound surfaces across the testicle in addition to stitching the sac to the wound on each side of the incision. In twenty-four hours the dartos had relaxed and the skin sutures were cut and the packing placed in the much-contracted sac. Prompt and satisfactory obliteration of the sac resulted and the man became entirely relieved of his distress.

This case probably was one of true fibrous or loose body originating from the hydatid of Morgagni or fœtal remains.

Conclusions.—1. Probably fibrous bodies are more frequently present in hydroceles than has been suspected.

2. Probably they rarely originate by hydroceles.

3. Probably their presence occasionally prevents the radical cure of hydroceles by irritant injections.

4. Fibrous bodies are to be suspected in small, painful hydroceles—particularly those which have promptly recurred after irritant injection or where excessive pain or inflammation or both have succeeded the injection.

5. That when the bodies are present nothing short of their removal by incision and through exposure of the interior sac will give relief.

6. That the possibility of their presence is an additional and strong argument in favor of the only thorough and certain radical cure for hydrocele, namely, incision and packing with iodoform.

## THREE SUCCESSFUL CASES OF VAGINAL HYSTERECTOMY.

W. H. WATHEN, M. D., Louisville, Ky.

I will exhibit three uteri removed by vaginal hysterectomy for malignant disease beginning in the cervix, two of which I removed last week. The first was removed a little over a year ago and the woman is now in perfect health with no local evidence of any recurrence. I exhibit this specimen because of that fact, and because it shows a more limited extension of disease than the other specimens.

The disease was limited to the posterior lip of the cervix and the vaginal walls for a half inch, necessitating cutting about three-quarters of an inch behind the cervix nearly to the bottom of Douglas' pouch to remove all the diseased structures. The cancerous disease was curetted away as well as possible before extirpation of the uterus. There was nothing unusual in the operation, but ten days afterward the nurse in giving a vaginal douche injected a pint of bichloride solution into the peritoneal cavity. I do not know the exact strength, but it must have been about 1-3000. This caused practically no trouble and the woman made an excellent recovery. But it impressed upon me the importance of avoiding vaginal injections after vaginal hysterectomy, unless we have, by suturing, positively closed the vault and united the peritoneal surfaces if such can be done. I have since had evidence in corroboration of this fact. I recently removed the gauze forty-eight hours after the operation and the omentum came down to the vulva. This was cleansed and returned with no trouble resulting. I do not believe vaginal injections will do any good and they may do much harm by getting into the peritoneal cavity, forcing necrosed and possibly poisonous structures in contact with the peritoneum. I depend upon drainage by gauze, and when this is removed wash the external parts and entrance to the vagina carefully; then with forceps use dry gauze and wipe out the vagina up to its vault; then re-introduce gauze, leaving to drain. By following this method I have had no trouble, and in fact I have not had for a long while any unfavorable symptoms, the patients going on to an uninterrupted recovery.

No. 2. This is a specimen I removed yesterday one week ago. The woman is now begging me to allow her to sit up; the pulse has remained normal, and I presume the temperature has also, because she has had so little evidence of fever that the nurse has not taken the temperature. She has had no distension of the abdomen and not the slightest evidence of sepsis. In this case you will observe that the disease involved the cervix extending up to the fundus of the uterus, which, of course it was impossible to determine until the operation was done and the uterus cut open. All diseased tissues were taken away by dividing the vagina beyond the diseased line.

No. 3. In the third specimen you will observe that the disease does not extend into the body of the uterus, but is limited to the neck going up to the internal os; still there was decidedly more destruction of the cervix than in the case where it extended into the body, showing that we are unable by any examination to detect how far the disease extends. If we do a high cervix amputation, as is advocated by a few of our good operators, we cannot know whether we have removed all the disease, and the only way of being positive that we do is by total extirpation, which is as easily done as the high cervix operation, and with an experienced operator very little more dangerous, for the immediate mortality of extirpation of the uterus is now with the best men very low—probably not exceeding five or six per cent.

About two and a half years ago I had the misfortune to lose a patient after vaginal hysterectomy, the result of sepsis, evidently conveyed to the peritoneum from the cancerous tissues upon the cervix. I immediately recognized the necessity of removing all necrosed tissues before the operation, so as to avoid the danger of sepsis from that cause, and also the possible danger of cancerous infection of the cut surfaces. Two or three days before the time appointed to perform the hysterectomy I gave an anæsthetic and thoroughly curetted the cervix and the uterine cavity with bichloride solution and tamponed with gauze. After the patient is on the

operating table, having been thoroughly prepared by general baths and vaginal douches, and the vulva having been shaved, the vulva and vagini are again washed with soap and warm water, cleansed with bichloride solution, and the curettage repeated.

I will not go into the details of the operation further than to say that I use my hysterectomy forceps and clamp the ligaments. The forceps are removed within from thirty-six to forty-eight hours, though probably they might be removed without danger in twenty-four hours.

As I have stated, the last two patients have no untoward symptoms, and are now past the danger line; and while they will recover from the immediate effects of the operation, only time will demonstrate whether they will be permanently relieved, and if not, how long before there will be a recurrence of the disease. It has been my experience that nine-tenths of the cases of malignant disease that consult me are beyond operative measures, the disease having extended to structures that cannot be removed or caused general infection. Those cases where the disease arises in the body of the uterus, if treated early, are more favorable in permanent results.

## THE TREATMENT OF DIPHTHERIA.*

G. BENSON DUNMIRE, A. M., M. D., PHILADELPHIA, PA.

There is, perhaps, no subject at this time exciting more and deeper interest in the profession, certainly there is none more important than the management of cases of diphtheria. In this connection some general remarks seem necessary with reference to the ravages of the disease. The excess of deaths over births, which is depopulating the French nation to-day, is largely due to diphtheria. In England it is not confined to the large cities alone, but the rural districts are feeling its scourge.† The same may be said of the United States, where there is a growing dread of the disease and justly so, because of the gradual increase of cases, and deaths as well, which quite an extended correspondence with the different State Boards of Health, also the mortuary registers show, conclusively proving two things: 1, its infectiousness; 2, that the general efforts now put forth to stay its progress are inadequate.

As to its infectiousness in man, this has long since been settled in the affirmative and the question now is, what creature is not subject to the disease? since flying fowl, creeping beast, as domestic animals or pets, are susceptible, and, like flies, have the credit of conveying the disease. The cat's ability to contract and transmit diphtheria to persons has long been observed.‡ Animal susceptibility to inoculations with diphtheria exudate and cultures of the same, has frequently been utilized; making them the experimenting ground by which important data have been obtained; settling the question as to whether diphtheria is primarily a local or a constitutional disease, in favor of the former. This has been proven by the elaborate investigations of Wood and Formad, Klebs, Loffler, Abbott, Welch and many others. But for the specific cause of the contagion we are indebted to Loffler for his discovery of the diphtheria bacillus, which bears his name. And no less important are the investigations of Abbott and Welch, who have established the fact that in the Loffler bacillus, we have the etiology of diphtheria, a factor of paramount importance in regard to its rational treatment and prophylaxis, again to be referred to.

With reference to the present effort not being adequate to stop the progress of the disease, we have to say that while this is true generally thoroughout the States, we are glad for one single exception which stands out conspicuously and alone, and is worthy of our respect and emulation. We have reference to Michigan and its State Board of Health, backed as it is by legislative enactments, not only requiring

* Read in the Section on Diseases of Children, American Medical Association, 1894.

† Thorne Thorne's Work. England.

‡ Noah Webster's Epidemic and Pestilential Diseases.

scientific investigative of disease and tabulating the same, but by an enforced system of isolation and disinfection, which has reduced, in 1889, the average number of cases per outbreak from 11.66, in which isolation and disinfection was negelected, to 1.56 when it was enforced, and deaths were reduced from 2.65 to 22,§ showing very plainly that the disease cannot only be controlled, but that there is a possibility of stamping it out entirely. Until other States are guided by the State of Michigan, they will continue to write large bills of mortality; which brings us to the vital question of

ISOLATION.

In the management of cases of diphtheria, after what has been said it seems unnecessary at this date and time to do more than refer to the excellent restrictions and preventions, even to minute details, issued and gratuituously furnished by a number of the State and local Boards of Health. But the great necessity is to have *enforced isolation.* Isolation, if not efficient, is no isolation at all. For instance, to quarantine the house is not isolation, when there is only a board fence or a wall to scale, between the quarantine and coverted liberty. Neither is it isolation, even against the physician's protest, for a mother of a poor family to separate and nurse one of her children sick with diphtheria in a down stairs, badly ventilated room, from the vitated atmosphere of which she emerges to supply the others with the food which the husband is compelled to be absent to provided; for soon the whole family becomes a prey for the disease. To meet such an emergency one of two things is necessary; a nurse must be provided by the health authorities, or the patient removed to a hospital adapted especially for contagious cases. Hence the great need for the latter, and provision for the former. Therefore, to have efficient isolation we must have the State's legal enactments and popular support, as well as public and private cooperation, all of which will follow in the wake of an enlightened judgement and a just appeciation of the great responsibility which one individual owes to another, and the public at large.

In view of the importance of isolation, as well as the trouble and inconvenience attending, the questions arising, What cases shall we isolate, and how shall we discriminate? are immediately forced upon us. Some cases of sore throat having an exudate are contagious and some are not. Under such circumstances it is always safe, particularly during an epidemic, to look upon all such with suspicion and treat the same as diphtheria, at the same time securing some of the exudate for microscopic examination, to determine as early as possible its true character.

The Klebs-Löffler bacillus is the only micro-organism always and persistently present in the exudate which, if found, establishes the diagnosis.‖ To do this satisfactorily will require a microscope with a one-twelfth oil emersion objective, and in some cases the bacillus may be detected by simply straining from one-half to three-fourths of an hour a film of exudate previously spread on a cover-slip in a 2 per cent. aqueous solution of gentian violet, wash in a 5 per cent. solution of acetic acid, then in distilled water, dry in air and mount, preferably, in Canada balsam.* This plan, however, may be confusing just at a time when it is desired to be positive. To establish which, the inoculation of a culture fluid with a portion of the exudate will be necessary, which after about eighteen hours in the incubator, if successful, will under the microscope reveal the character of the bacillus, which culture, if desired can be used to ascertain its pathogenic properties by inoculating a rabbit or guinea pig. If the practitioner is fortunate enough to possess a good microscope, culture incubator and other appliances, he may possibly settle the question in doubtful cases. If not he should send a sample of the exudate on clean, white paper, securely bottled, to a competent bacteriologist, who can in twenty-four hours determine its nature. Every Board of Health should have such a salaried appointee to carry out such investigations. It having been determined that the case is one of diphtheria the patient is isolated, if he has not already been, in the upper story of the house which has been previously cleaned and divested of all drapery, upholstery, carpets and everything excepting the barest necessities for the proper

§ Restriction and Preventions of Diphtheria. Michigan State Board of Health. Printed 1892.

‖ Annual address on the Causation of Diphtheria, by Wm. H. Welch, M D. Transactions of Medical and Chirurgical Faculty of Maryland.

* Loffler's Method.

care and comfort of the patient, and at the disposal of the attendants, for more than one will be required in severe cases.

They should be furnished with one or more large pails containing a 1-1000 disinfecting solution of corrosive sublimate, into which bed linens and garments of whatever character should be immersed before taken from the room. Being free from the rattle of tin, two marked papier-maché basins, one to contain the disinfecting solution before mentioned, as the best in our judgment, and the other for water convenient for the attendant's ablutions after necessary contact with the patient. Two or more covered chamber buckets, one always near containing a quart or more of a solution of chlorinated lime in strength of half a pound to a gallon of water, for the reception and disinfection of alvine dejections and promptly removed from the room, but allowed to remain in the bucket two or more hours before emptying into the closet. In this connection there should be a liberal supply of towels and soap with a view to the absolute cleanliness of the person and the surroundings. A spitting cup containing an 8 per cent. solution of carbolic acid to receive the secretions and expectorations from the mouth, throat, lungs and nose; or a better plan is to receive such material on soft muslin rags, toilet paper or small squares of cheese cloth, immediately burned. Hence, the necessity in the room of an open grate, or stove, in which such expectorations can be cremated. Such secretions being the most infectious, because containing the diphtheria bacillus, should be most carefully guarded and utterly destroyed. In absence of an ordinary stove, a gas or perhaps the objectionable coal oil stove, on which, with a view to prevent dryness of the air in the room and to disinfect the same, a vessel containing the following should constantly be kept simmering, a modification, we believe, originally suggested by Dr. J. Lewis Smith, N. Y.:

℞ Ol. cinnamoni ..... 30 parts
Ol. eucalyp..... .....180 "
Acid carbolic.....220 "
Ol. terebinth..... .....420 "

M. Use one ounce to a quart of water.

An adjoining room should be appropriated to the use of the attendants, to the door of which needed supplies should be brought, and from which disinfected articles be removed for further disinfection with boiling water. The visits to the kitchen by the attendants, where other members of the family are, perhaps children, should not be allowed. To, or in this room, provisions can be brought and prepared as ordered for the patient, which brings us to the subject of

FOOD.

In order to support the strength of the patient, the proper nourishment is a matter of the most vital importance. Though anorexia is generally persistent, systematic feeding should be instituted early, and of such character as is suitable to the age and condition of the patient. Fluid nourishment being most tolerant to the stomach; as milk, warm or peptonized, cold milk, beef juices expressed from broiled beef, beef peptonoids and other food more concentrated, as eggs, soft boiled, eggs and milk; and when stimulants, which are required early in severe cases, eggs and milk beaten up with brandy, also milk punch, should be judiciously given.

In those cases where there is an unwillingness, or as is frequently the case, an inability to swallow nourishment, enemata of the articles just mentioned should be resorted to early, freely and continuously, until convalescence. This cannot be emphasized too forcibly, for by the early and continued support and maintenance of the vital powers, we thereby assist nature to resist and withstand the septic influence of the disease, and thus we often accomplish more than by over-much medication.

LOCAL TREATMENT.

The necessity for seeing diphtheritic cases early cannot be over-estimated, and in our judgment should justify the request, on the part of the family physician, for a speedy summons in time of sore throat epidemics especially; for success in a great measure will depend upon the local treatment being employed early, vigorously and with a view to destroying the diphtheria bacillus and preventing the absorption of the poison, now known to be tox-albumen. To accomplish this desirable result in

PHARYNGEAL DIPHTHERIA:

First, disinfect the throat; and second, remove the exudate as fast as it forms:

To accomplish this, begin by spraying the throat with a 1-1000 aqueous solution

of mercuric chlorid, using one of the many atomizers, or if the child is sufficiently intelligent have it gargle with the same solution, which will make the throat safe to work with, to be repeated every three or four hours. Then by means of brush or cotton swab, patiently and with care dissolve the exudate, by applying the following:

℞ Papayotin or trypsin* ..... gr. lxx
Hydrar. chlo. cor. ..... gr. ¼
Aqua distil ..... f. ʒ iv
M.

Apply every half hour until the membrane is dissolved; and at the same time every half hour alternately, disinfect the throat by using one of our safest antiseptics; the peroxid of hydrogen, though not a germicide†, accomplishes the same result by interfering with the development of the bacillus. Spray the throat, using from one-half to 15-volume solution or full strength, which will aid in dissolving the exudate in its formative stage, but fails to do so later, when imbedded in necrotic tissue, for which reasons these applications should be faithfully applied, not even allowing the patient's sleep to interfere; for very frequently the fate of the case depends upon the first twenty-four hours of local treatment, which if persistently and efficiently done, we have reason to believe that the septic influence of the bacteria may be prevented, and instead of a lingering case, we will have a a rapid recovery of the patient. We, however, cannot afford to confine our remedies to one or two, but suit the remedies to the case; hence, another very valuable and safe disinfectant and good antiseptic successfully used, where the other might be inapplicable, is a ten grain solution of the nitrate of silver. The solid stick or even a too strong solution, makes it difficult to distinguish the resulting coagulated albumen from the diphtheritic exudate; besides, we have thought that its frequent application tended or predisposed the inflamed mucous membrane to a necrotic condition finally resulting in hemorrhage.

The forcible removal of the exudate and the application by means of cotton wrapped on a pincett, of the following:

℞ Camphor ..... 20 parts
Castor oil ..... 15 parts
Alcohol ..... 10 parts
Carbolic acid ..... 5 parts
Tartaric Acid ..... 1 part
M.

* The best at our command.

† George M. Sternberg, M. D., on Disinfection, Hare System of Practical Therapeutics.

is recommended by Grancher‡ also Dr. Turner of Glasgow, suggests a similar treatment but uses the application of parafin. Being painful the treatment though successfully used in adults, is inappropriate with children, and further the danger of absorption from the wounded surface would be increased. The same objection would apply, it seems to us, to Dr. August Seibert's disc of hypodermic points, through which chlorin water is injected to destroy the bacillus, as it is now known that the bacilli are mostly on the surface of the membrane.

Since the use of corrosive sublimate, first by Billotte in 1876, it seems to be growing in favor. Rennert, of Germany, reports repeated successes, by wiping off the exudate with the following:

Hydrarg. chlo. corrosiv. ..... 1 part
Acid tartaric ..... 5 parts
Aqua ..... 1000 parts

The remedy is being largely used in England.

In very young children, the repeated insufflation of washed sulphur, an application which can be thoroughly made where we fail with many other applications, by simply using a glass tube. The good resulting may be attributed to the disinfecting properties of sulphurous acid, set free by the oxidation of the sulphur.

As a topical remedy, we have used the perchlorid of iron in combination with glycerin, equal parts. In hemorrhagic cases it does well. With many it is the principal local treatment.

Carbolic, boracic and salicylic acid, have their appropriate use as antiseptic gargles and sprays, but as every intelligent physician has his own way of using means to ends, these, with many others, if time permitted, could be named as suggestive of the fact that it is unwise to restrict our remedies, but treat each individual case, not the disease. Keeping in view and preventing if possible, the tendency of the disease to extend to the larynx as well as to the posterior nares. If to the latter we have

NASAL DIPHTHERIA.

The nasal passage may be the primary seat of the disease; frequently, however, it is the extension of the pharyngeal affection. This complication is recognized by the forced mouth respiration, the nasal passages being closed by the swollen mucous

‡ Le Progress Med., Sept. 27, 1890.

membrane which is covered with a grayish white lining, discharging a thin acrid muco-purulent discharge which, later on, becomes greenish-yellow tinged with blood.

The glands in the neck soon become involved, with earlier constitutional involvement than in the simple pharyngeal variety. These unpleasant cases are difficult to manage on account of the intricate nasal passage which should be disinfected early by douching and spraying the nasal fossæ.

The former can best be done by means of a perforated flexible rubber catheter, attaching the same to any ordinary syringe, and by bending the patient's head forward, the nasal cavities can be thoroughly and effectually douched, preferably with the peroxid of hydrogen, every three or four hours.

The nasal passage may be sprayed with the same remedy, also with a weak solution of carbolic acid, or the corrosive chlorid, but some instructions to the inexperienced attendant will be necessary to the careful introduction of the nozzle of the atomizer, keeping it on a level with the floor of the nasal fossæ and parallel with the septum, so as to prevent wounding and the resulting hemorrhage. The greatest cleanliness should be observed in these cases, using the 1 : 1000 chlorid wash, and the cremation of all nasal discharges. But as intimated the exudate may extend to the larynx and the result is the most dangerous phase.

### LARYNGEAL DIPHTHERIA.

Though the duality of membranous croup and diphtheria is not absolutely settled, yet the fact of their unity being so regarded by physicians generally and acted upon approvingly by boards of health, is accomplishing good as a check to its spread. The bacillus may primarily attack the windpipe, but, like the nasal form, it is frequently the extension of the disease into the larynx. Its commencement may be recognized by a hoarse croupy cough with aphonia, and later a gradually increasing dyspnea. These symptoms sometimes subside in a few days under the internal treatment of bichlorid and spray of the same from a steam atomizer, also lime water and 2 per.cent. solution of carbolic acid, or the steam from lime slacking in any ordinary vessel having a perforated lid, to which a tin tube or pipe can be conveyed into a tent constructed over the child—not forgetting proper ventilation—or to the mouth of the patient. We cannot expect, however, as much from our spraying and local applications which are so beneficial in the laryngeal and nasal form of the disease. In this connection and in this form of the disease, we wish to call attention to a remedy the results of which have been recently so satisfactory as to justify further trial, namely, oxygen. It should be given early because of the better oxidation of the blood. The increased tone and strength, both to the nervous and muscular system resulting from the improved condition of the blood, allays nervous irritation and excitability and produces sleep, all of which tends to assist the vital powers of the system to battle with the disease. Three inhalations in succession of about twenty seconds each, allowing the gas to pass through a jar of antiseptic water, should be given three or four times daily, or oftener, when there is labored breathing or a cyanotic condition. But should the dyspnea increase, preparation will have to be made to intubate or perform tracheotomy, which leads us into the domain of surgery, upon which it is not our purpose to enter, further than to state that either operation gives the patient about equal chance. Dr. Stern makes the per cent. of recoveries of the former 26 2-5 per cent. and the latter 26½ per cent. The same author recommends intubation under three and a half years of age, and after that time the preference is for tracheotomy, excepting adults. Dr. Montgomery, however, who has had a large experience in intubating, writes us that he has had 44 per cent. of recoveries. But in our treatment we should not forget

### CONSTITUTIONAL REMEDIES.

Just how soon the poison of diphtheria is taken up by the absorbents, and how much or how little is required to contaminate the system, we have no reliable means of determining. That it is absorbed very rapidly we have only to recall the cases in our experience of heart paralysis after a few days of illness, and the amount to produce septic influence may depend largely upon the susceptibility of the person. But Welch and Flexner have shown that 2 cc. of filtered culture fluid contained toxic properties sufficient to kill a guinea-pig. So it is well to begin internal remedies early,

and we can make no mistake by giving the chlorid of iron and quinin in large doses suitable to the patient three or more times daily, so as to obtain not only the tonic effect of both, but the antiseptic influence of the iron; or alternate or substitute for the iron the following:

℞ Hydrar. chlo. cor.....grs. jss. (1½)
Syr. aurant rub.....
Aqua ää.....f ʒ j.
M.

Take from one-half to a teaspoonful every six hours. The object being as Dr. Jacobi suggests, "to have its specific counteracting effects on the diphtheritic poison in the system."

Chlorate of potash is looked upon with less favor than formerly, because of its unfavorable action upon the kidneys.

Complications or sequelæ of diphtheria in the form of paralysis of the uvula, arms, or legs, can best be relieved by general tonics, change of air; we have found a sojourn by the sea of great benefit. Obstinate cases yield to hypodermic injections of strychnia, from 1.20 to 1.60 gr. three times daily. Electricity will also be of service.

Instead of summing up conclusions, allow us to say a word in reference to our future hope—

PROPHYLAXIS.

1. Against personal infection, physicians and attendants should gargle the throat, wash the nasal passages, face and hands before and after visits, in 1-1000 solution of corrosive sublimate, and nothing short of a change of garments is excusable in going from a diphtheritic case to other patients.

2. This paper would be more incomplete than it is, did we not refer to what modern bacteriologists are accomplishing for us, particularly concerning the prevention and cure of the toxic products producing the morbid symptoms which we more or less see in every case of diphtheria.

Dr. E. A. De Schweinitz, Biochemic Laboratory, Washington, D. C., replying to our query, writes: "Experiments in this country and abroad have demonstrated that a substance (albumose) exists in and can be isolated from the cultures of the diphtheria bacillus which produces, when injected into guinea-pigs, immunity in those animals from this disease." Hardly had we begun to ask the question, why can not this immunity be safely rendered to man? when we learn from Germany that "blood serum" from immunized animals is an anti-toxine which gives immunity to the individual, and that Dr. Aronson, of Berlin, claims for his blood serum immunizing strength of 1-10,000 for guinea-pigs; for children weighing forty-four pounds; 4 ccm. given subcutaneously, which doses afford positive protection if injected before infection; being inefficient in the disease's later stages.

But "later investigations, particularly Behring, have proved that this property of blood serum to counteract the bacterial poison may be progressively intensified, so that by repeated inoculation, a complete immunizing strength can be obtained, potent even against super-virulent bacteria cultures. The injection of blood serum from such animals afforded not only protection against virulent infection, but aborted the already present infection and made it harmless, and therefore proved *a specific cure* for the indicated disease." If these facts can be established in this country and elswhere, surely the "goal of therapeutic effort" is reached and the glory for the second Jenner is in reserve.

---

A Long Fast.—Russian newspapers report the case of a girl, seventeen years old, who was overtaken by night, and being afraid to go home in the dark, decided to pass the night under a *hangar* covered with a little straw. During the night a snowstorm occurred, and in the morning the girl found herself unable to escape from the load of snow which covered her. The first day she ate five morsels of bread which she had with her. After that she had no other nourishment than the snow which imprisoned her. It was not until the end of *fifty-one days* that she was discovered and taken to a hospital. Although unable to move, she could answer questions. She made rapid progress, and at the end of the first week could take the ordinary diet of the hospital.

---

Conceptions just previous to the menstrual period result in boys; those just after, in girls. Such is the conclusion from many observed, notably among the last by Dr. George Abbott, who publishes his opinion in the *Medical Record.*

# TRANSLATIONS.*

## THERAPEUTICAL SUGGESTIONS FROM FOREIGN JOURNALS.

### IN-GROWING TOE-NAIL.

Dr. C. Huebscher, (*Correspondenz-blatt f. Schweizer Aerzte*, No. 54, 1893), observing that neither removal of the nail nor excision of the lateral grooves will hinder recurrence of in-growing toe-nail, while local application of caustic potash is not radical and excision of the whole bed is apt to be succeeded by a granulating surface that requires time to heal and is liable to try the patient's patience, has tried to overcome this difficulty by removing the entire bed of the nail and covering the defect by a skin flap according to Thiersch, in order that healing follow by first intention. He proceeds as follows: an injection of a cocaine solution is made into the toe, the nail is split and both halves evulsed, the two lateral folds cut out and the posterior portion excised that an even and fresh wound surface result. The whole bed of the nail is then freshened up with the knife held on the flat. The hemostatic bandage is then loosened, the hemorrhage controlled by means of a tuft of gauze and a thin layer of skin cut from the surface of the thigh and transferred to the wound. As a dressing, strips of gauze, dipped into a solution of iodoform in olive oil, are employed, over this cotton and then gauze. The patient is kept in bed and after two to three days the dressing is then changed. Healing usually takes place, by first intention. A protective against friction may be given by covering the toe with an investment of iodoform gauze and collodion.

### TREATMENT OF ABORTION.

Dr. Czempin, (*Wiener Medizinische Presse*, No, 44, 1893), warmly recommends prophylaxis for, in spite of hemorrhage, the fetus may still be able to continue its development. The greatest quiet, and above all, rest in bed are to be observed during the time corresponding to the menstrual epoch, for then the inclination to hemorrhage is greater. A cause less frequently thought of as inducing abortion, is the existence of cicatricial adhesions binding the uterus to its surrounding tissues and organs, after preceeding pregnancies; cervico-vaginal lacerations and their cicatricial adhesion to the surrounding tissues and the residua of parametritic exudates. Abnormal fixation of the uterus to the lateral pelvic wall may also hinder the organ in rising up into the abdomen, in the third and fourth months. Violent colics are thus produced which can not be traced to any palpable cause, and are often difficult of explanation. The influence of the interabdominal pressure, with the movements of the body, lead to hemorrhage into the mucous membranes and consequent abortion. Even under such conditions, by rest in bed and care, one may surmount this critical period in the third to the fourth month. Treatment must consist in removing all the harmful influences. Three classes of abortion may be distinguished:

Incipient abortion.—The fetus and placenta are yet retained in the uterine cavity in spite of pains and hemorrhages.

Incomplete or protracted abortion.—The fetus is expelled and the placenta or portions of it are still retained. Here there are liable to be severe hemorrhages or ill-smelling discharge and fever.

Complete abortion with hemorrhages from the mucous membranes. The fetus and placenta are expelled, the uterus slightly enlarged, with continuous slight hemorrhages or bloodily tinged serous discharges, from incomplete throwing off of the decidua.

The first group, which is relatively rarely observed, demands careful expectant treatment, and with severe hemorrhages, acceleration of expulsion. Tamponading the cervix, with strips of iodoform gauze, will both dilate and excite contractions. Introduce them up above the internal os and if necessary renew the proceedure. Manual evacuation, if called for.

The second class is the most frequent and dangerous. The severe hemorrhage, with the succulent, soft and enlarged uterus and the open cervical canal, call for immediate digital evacuation of the uterine cavity. If the cervix be closed, dilate. The dull curette should only be employed after previous dilatation and the sharp

*Translated for The Medical and Surgical Reporter by F. H. Pritchard, M. D.

curette never. Ergot is here contra-indicated as residua, even if of large size, are not influenced by strong contractions. He recommends tamponade for twelve hours before evacuation, as it causes softening of the cervical tissues and greatly facilitates forcible dilatation. If there is neither severe hemorrhage nor fever, employ the gauze tamponade, otherwise force dilatation. This is best done by introducing a Simon's speculum, fixing the cervix with a tenaculum and slowing introducing Hegar's dilators, under anesthesia, if necessary. When the cervix easily opens up, the finger is introduced, all portions of the uterine cavity are searched over and the placental residua removed.

The third group is often too energetically treated, for spontaneous expulsion often follows later. Even if none of the secundines are cast out, one may safely wait twenty-four hours in recent cases. The firmly contracted uterus shows that the placenta is expelled and that only the decidua remain. The dull curette may be employed without dilatation. In the greater number of cases a few doses of ergotine will generally suffice to induce their being expelled. It is injudicious to curette after each and every case of abortion without having examined the parts thrown off.

---

### CONFUSION OF GASTRIC AND INTESTINAL DYSPEPSIA.

Prof. Germain See (*La France Médicale*, No. 52, 1893) claims that a third of those patients who were thought to be dyspeptics and of stomachic origin are actually sufferers from intestinal disease. This holds good especially, in women, for a careful examination both by physical and chemical diagnostic measures reveals good gastric function and no dilatation, while they have gone from one physician to another and have been treated for dyspepsia. These dyspepties are not suffering from a gastric disease, for their whole trouble lies in the intestine and pre-eminently in the large intestine. It deserves the name of muco-membranous enteritis. The small intestine in such cases is healthy. This muco-membranous enteritis is characterized by disturbances in the functions of the colon, gaseous fermentation, dilatation of this intestine, but nothing reveals it with certainty other than the passage of mucous glairy, ribbon-shaped or cylindroid masses, with the feces often unperceived. These mucous products are also frequently accompanied by the hardened residua of undigested food. Treatment consists in evacuation by mechanical means, as olive oil or senna, but not by purgation, calming the pains by the bromide of calcium or strontium or cannabis indica but not by opium and its preparations. Fermentation and the formation of gas may be limited by the phosphate, the biborate or the salicylate of soda, never by benzo-naphthol. The diet is that of one in health except that the presence of habitual constipation or incidental diarrhœa alter it. In general, hearty foods as ham, pork, game, boiled eggs are easily digested, while milk is tolerated with difficulty. Potatoes, either mashed or boiled, as well as rice, are easily digested though fruits are of no advantage. Water and tea are permissable as beverages. Gaseous waters are contra-indicated on account of their containing carbonic acid gas. Alcohol, being in large measure absorbed by the stomach, is best left alone unless temporarily, when digestion is bad. Then a hot sling is of service, while red and white wines are not to be allowed.

---

### NITROGLYCERINE IN POISONING BY ILLUMINATING GAS.

Dr. Hoffmann (*Deutche Medicinsche Wochenschrift*, No. 50, 1893) has employed subcutaneous injections of nitroglycerine in cases of poisoning by illumination gas, with the best of results. He injects from one hundred and twentieth, to an eighth of a grain every twenty minutes. Others have confirmed this.

---

### GONORRHŒAL CYSTITIS.

Dr. Okeblom (*Deutsche Medicinische Wochenscrift*, No. 35, 1893) in cases of cystitis, and more especially where it is of gonorrhœic origin, injects every second to third day, one to six grams—fifteen drops to one and a half drachms—of a solution of iodoform in ether and olive oil—1:7:7—by means of a Guyon syringe. The pain and tenesmus cease at once.

---

### UNTOWARD EFFECTS OF IODOFORM.

Prof. L. Lewin (*Hospitals-Tidende*, No. 31, 1893) devotes an extensive article to

the side and after-effects of iodoform. On the skin, in some cases acne and purpura, have been noticed after its internal use. Cutaneous symptoms are frequent and are chiefly, though not entirely, due to its local use. Local dermatitis is the form most often noticed, though it may extend more or less over the body in exceptional cases. This eruption may be either eczematous, vesicular, pustular, impetiginous, or erysipelatous and often accompanied by high fever. In other cases, extensive erythematous eruptions, with formation of bullæ or purpural patches as well as urticaria or papules have been observed. Intense itching may complicate and the dermal phenomena last for several weeks.

Conjunctivitis, transient amblyopia, alterations in the pupils and strabismus are recorded. Among the symptoms are mental alterations which either exist alone or are the forerunners of graver psychoses. In most cases they assume the form of melancholy, with anxiety, uneasiness of mind, inclination to tearfulness, tiredness of life and restlessness which very frequently alternate with periods of excitement. This may be associated with vertigo, headache, elevation of temperature, sleeplessness and small and rapid rise of pulse. The pulse may, without disturbance of the general health, run up so as to become uncountable while the temperature remains normal. The temperature may also rise and continue for several days at this elevated condition, several degrees over the normal, without the patient experiencing a feeling of illness. This increase of pulse, without accompanying fever, is a threatening symptom in elderly people.

Melancholia, the chief expression of its mental action, when once it has appeared, is prone to persist. It is accompanied by hallucinations, visions, illusions and anxiety which are expressed in the delirium of persecution and in the attempts at suicide. These patients, as a rule at night, but even during the day, suddenly will jump from their beds, try to spring from their windows, to escape or to throw themselves into the water. They attempt to tear off their bandages, destroy the bedclothes, talk confusedly, stamp their feet, rage and do not recognize their surroundings. This condition may last from a few hours to days and pass off into a more morose and tearful state, which soon ends in recovery. They remember nothing of the attack and present pure types of transitory mania. In some cases the depression increases in intensity, and a completely stuporous state of melancholy developes, with refusal to take food, rapid decline and death. Seizures of anxious excitement and choreiform attacks, loss of appetite, and violent vomiting have also been noticed after the use of this antiseptic. In men and animals poisoned with it, no pathological alterations are found in the brain and its membranes, but only fatty or parenchymatous degeneration of the heart muscle, liver and kidneys.

---

### ACNE.

Dr. Phillipson (*Hospitals-Tidende*, No. 50, 1893) recommends in acne the following lotion:

℞ Acetic acid,
Tinct. benzoin,
Spirits Camphor, ana..... 6 gms. (℥jss).
Alcohol.....82 " (℥ijss).
Apply locally morning and evening.

---

### VINEGAR IN VOMITING AFTER CHLOROFORM.

Dr. Warholm (*Hygiea*, No. 10, 1893) has employed vinegar with success in the treatment of vomiting after anesthesia by chloroform. He dampens a cloth with the liquid and places it near the patient's nose, allowing it to remain there until he awakens, or even longer if vomiting then threaten. He warmly recommends its use.

---

### CHRONIC URTICARIA.

In the (*Hospitals-Tidende*, No. 44, 1893), the following salve is advised in the treatment of chronic urticaria:

℞ Chloral,
Powdered camphor,
Gum arabic, aa.....5 gms. (℥j¼).
Simple cerate.....40 " (℥j¼).
Rub in well every evening.

---

### ANEMIA IN NEURASTHENIA.

Prof. Gram (*Hospitals-Tidende*, No. 47, 1893) employs the following formula:

℞ Citrate of iron and quinine...5 gms. (℥j¼).
Distilled water..... 200 " (℥vjss).
Brandy.
Syrup, ana.....50 " (℥jss).
A tablespoonful three times a day.

---

### GASTRIC SYMPTOMS OF NEURASTHENIA.

Drs. Rummo and Braccini (*La Semaine Médicale*, No. 54, 1893) employ the following formula:

℞ Phosphide of zinc..... 1 gm. (grs. xv).
Bromide of zinc..... 1 " (grs xv).
Bromohydrate of quinine..1.5 " (grs. xxij).
Extract of nux vomica.....15 cgms. (grs. ijss).
For thirty pills. Three per diem.

TERMS:—Three Dollars a year, strictly in advance. Sent four months on trial for $1.00.

REMITTANCES should be made payable only to the Publisher, and should be made by Postal Note, Money Order or Registered Letter.

NOTICE TO CONTRIBUTORS:—We are always glad to receive articles of value to the profession, and when used they will be paid for, or reprints supplied, as the author may elect. Where reprints are desired, writers are requested to make a note of that fact on the first page of the MS. It is well for contributors to enclose stamps for postage, that the articles may be returned if not found available.

SATURDAY, FEBRUARY 10, 1894.

## EDITORIAL.

### INFLUENZA.

"Oh, I have pass'd a miserable night,
"So full of fearful dreams, of ugly sights,
"That, as I am a Christian, faithful man,
"I would not spend another such a night,
"Though 'twere to buy a world of happy days,
"So full of dismal terror was the time."

—*Shake.*

When the present epidemic was beginning to make itself evident in this country, the average physician was prone to regard *La Grippe* as a fashionable euphonism for cold in the head. After a personal experience with the disease, the average physician is apt to remember *La Grippe* as an avalanche of outer darkness, overwhelming the physical energies, paralyzing the mind and plunging the spirit into an abyss of misery that gives a new and vivid meaning to the despairing cry of fallen Lucifer:

"Which way I fly is hell; myself am hell,
"And in the lowest deep a lower deep,
"Still threatening to devour me opens wide;
"To which the hell I suffer seems a heav'n."

Influenza presents probably a greater variety of symptoms and manifestations than any other known disease. On the one hand it appears as a transient cold in the head, while in its graver forms it may strike down its victim with the utmost rapidity, or so completely prostrate his mental and physical powers as to invite insanity and even suicide.

Dr. Guiteras thinks that a safe answer to the question "What is influenza?" would be, "An epidemic cold depending upon some yet unknown cause." This is more general than it is satisfactory, but it is doubtful if a more exact definition can be given.

Guiteras says (*Med. Rec.*) concerning its etiology:

"Predisposing influences, none. People are attacked without distinction of age, sex, occupation, or social standing. Previous or present illness affords no protection. One attack renders no immunity from another. Overcrowded, unhealthy, badly ventilated, and damp dwellings render attacks more severe, although the dwellers are no more prone to it. Influenza may occur in any season. It occurs usually in the autumn, often in the spring, and sometimes in the summer and winter. Latitude has no effect, as in the epidemic

of 1837 it appeared at the same time in England and Cape Colony, that is, in directly opposite zones and seasons. Climate has no influence, as it occurs equally in the dampest and driest regions. Certain meteorological signs and coincident phenomena have been remarked as preceding many of the previous epidemics, such as foul fogs, volcanic eruptions, earthquakes, etc.

"The rapidity with which it spreads and the great numbers who suffer from it at the same time and in the same way, certainly point to some specific poison which is carried by the air as a disseminating medium and excites the disease. This poison was supposed by many for a long time to be the sulphur and other matter thrown from the volcanoes, which was carried about in dust-fog currents, a foul fog having been generally noticed before an epidemic, or accompanying it. In this enlightened age, however, I think we are justified in believing that the exciting cause is a micro-organism.

"The investigations of the bacteriologists in searching for micro-organisms have resulted as follows:

"For several years the diplococcus pneumoniæ of Frænkel and Weichselbaum, the streptococcus pyogenes, the staphylococcus pyogenes aureus, and several scattering forms were the only ones found, until Dr. Pfeiffer, of Berlin, in 1892, discovered a bacillus in the secretions of patients suffering from influenza, which was declared by Koch, Kitasato, and others to be the true germ of this disease. This bacillus was about the thickness of bacillus mouse septicæmia, but only half the length. As only the two ends stain, it is very hard to distinguish it from the diplococcus and streptococcus. Former observers seeing these mistook them for the latter. They were cultivated by Kitasato and others.

About the same time Bruschettini[1] found the same germ in the blood of those suffering from the disease.

The question why an epidemic may break out at one time and then for years remain dormant is not an easy one to answer. It is probable that there are cycles in which peculiar seasons recur, and that such cycles are associated with the reproduction of similar disordered conditions in the health of man."

It occurs to us that influenza, at least in the more marked nervous forms of the disease, is essentially a neurosis of the central system, or else in these forms the bacillus or its products exercise a peculiarly toxic effect on the upper spinal system. This is on the assumption that the disease is essentially a germ disease, although the life history of the specific germ has not yet been declared.

By far the most common form of the disease is that in which the catarrhal symptoms predominate, and though protean in its manifestations, its sequelæ are not as disastrous as are those of the distinctly nervous type.

The prognosis, as regards life, is good in most cases. The disease is self limited, and with suitable treatment and proper care on the part of the patient, there is little doubt of speedy recovery. In the old and infirm, in those suffering from chronic diseases, in patients with Bright's disease or valvular disease of the heart, influenza is dangerous; very frequently fatal.

Treatment must be directed to the symptoms presented by each individual patient. On general principles, the bowels must be kept soluble; headache, fever and pain controlled by suitable drugs, but with the careful avoidance of such as tend to depress; stimulants must be used where necessary, but never in excess; while the system must be supported and built up by tonics and foods. Other indications must be met with as they rise. But there is one thing that should be im-

1 Ricerche bac. sull. infl. la communicazione preventiva. Riforma Medica, Gennaio, 1892.

pressed on the patient's mind. Influenza is a disease not at all amenable to the will power of the individual. Attempts to combat it by the exercise of will are only wasted energy, and the best means to insure a speedy recovery is absolute rest in bed from the time the disease makes itself evident, until the system has become habituated to its presence and has recovered itself enough to resist its inroads.

# ABSTRACTS.

## SOME THINGS THAT SHOULD NOT BE FORGOTTEN BY THE GENERAL PRACTITIONER.

B. C. KEISTER, M. D., South Boston, Va.

First, he should recognize his duty to himself, and second, his relationship to other physicians. I believe it was the late Dr. Flint who made the remark that "every physicians who is true to himself should be a thorough gentleman, a through business man and a thorough physician."

First of all, he should be in sympathy with the Christian religion; even if he is not a member of any special branch of the orthodox church, he should certainly not be a skeptic or an infidel. It would be exceedingly difficult for a skeptical physician to hold the confidence of one of his church-going patients through any serious illness, to say nothing of the many other disadvantages, under which he would have to labor. I may be pardoned for saying that we have in our ranks, men who are not only skeptical on religion but *peculiarly* so on the science of medicine. They delight to speak disparagingly of the science and are fain to show an air of ostentation that well characterizes the peacock or the *non compos mentis*. This latter class of physicians, to say the least, are unworthy of the title they bear; for to them is due the skepticism that exists among the laity on the science of medicine, and thus a great barrier is formed between physician and patient, to say nothing of the harm done to the credit of the profession. It is true there are wonderful changes constantly being made in the art of medicine, but generally speaking, these changes are only the steps toward a better and more perfect practice of the science. As man's constitution changes so must our practice change, in order to adapt its merits to man's necessities. Medicine is a progressive science. The advance that has been made in the past ten years in the science of medicine and surgery far surpasses that of all other branches of knowledge. Dr. Nicholas Senn, who is one of the progressive surgeons of the world, remarked to a large body of physicians a few months ago, that there had been more genuine progress made in the science of surgery within the past ten years than had been made during the previous one hundred years. Thus we see how grandly our great science is keeping abreast with all others, and I may add, since antiseptic surgery and electricity have come to our aid, we are fast outstripping all other professions on the broad road of progress.

All honor to such men as Koch, Pasteur and Sternberg, who have accomplished wonderful results in their researches with the microscope, in ascertaining the cause of disease. All honor to such men as Senn and Gerster, Loomis and Osler for putting into practice the teachings of the former, and thus bringing about a grand revolution in the practice of medicine. It is the duty of every true physician to hold up the standard of his profession. And to do this successfully, he should be both a thorough gentleman and a thorough physician. He should keep abreast of the times, by spending at least three months out of every three years at the medical centers, where hospital advantages are offered to the general practitioner as well as to the specialist. This is a duty that every true physician owes to himself. If every general practitioner would do this, he would be better prepared to do his work, instead of allowing his patients to go to the city

specialists to be treated for the very disease that he could have treated equally as well at home. It is passing strange that there are so many general practitioners, who from mere want of confidence in their own abilities, will send their patients to the cities to be treated by men who have had less experience and fewer collegiate advantages than they have had. I am acquainted with a physician who sends at least one-third of his cases to the city to be treated; these, doubtless, could be treated at home just as well. I claim that there is but one advantage the prominent city physician has over the town or country physician, namely, the hospital advantages, where good and skillful nursing is required after capital surgical operations. We need a few more McDowell's and Sims in the country villages to encourage us to compete with the city surgeons and city specialists.

I long to see the day when every village and country doctor will be as handsomely equipped in office facilities, etc., as any city specialists, and thus be prepared to treat his cases at home, instead of sending them with their pockets full of money to the city specialist. I am proud of the fact, that out of a yearly three thousand dollar office practice, I have thus far been able to treat my cases at home, and I mean to continue to do so as long as I remain in the practice of medicine. There is no just reason why every physician should not keep abreast of the times as above indicated, and be equipped with a full supply of the necessary surgical instruments, galvanic, faradic and cautery batteries, etc. There are many lives sacrificed, wholly on account of the attending physician not having proper surgical instruments to relieve the patient. To cite an instance of this kind:

About four weeks ago I was summoned fifteen miles in the country to relieve a man who was suffering from suppression of the urine, due to organic stricture of the urethra. The attending physician, who is a very clever man and a good doctor, did not have a urethrotome or any suitable bougies by which to relieve the patient of his intense suffering, and he had not passed scarcely any urine for the previous thirty-six hours; doubtless he would have died very soon from rupture of the bladder or uremic poisoning had he not been relieved. The pay received in this one case would have been sufficient to purchase two or three urethrotomes and a sufficient number of filiform bougies to last five years.

I claim that in nine cases out of ten it is *sheer stinginess* on the part of the physician, that he is not properly equipped with suitable instruments. Every physician should have in his office one good twenty-four cell galvanic battery, two good faradic batteries and one good galvano-cautery battery, ( I like McIntosh's batteries better than any other make). If he has studied electro-therapeutics and can master it well, he will find it a wonderful help to him in the treatment of diseases peculiar to women.

I am very much inclined to believe, that in the course of time electricity will take the place of the surgeon's knife in gynecology. I can testify to its proficiency in the treatment of fibroid tumors of the uterus, subinvolution and many other diseases of this class. Conservative surgery is yielding better results every day, and I believe the time is not for distant when women's ovaries will be let as severly alone by the abdominal surgeon as the Holy Bible. Away with the idea of a physician's reputation being gauged or made by the number of laparotomies he performs or the number of women he unsexes. It was my privilege a few months ago to be an eye witness to some ten or twelve laparotomines, and I must say, with all due deference to the skilled operators, that in my humble judgement, at least two-thirds of those poor women would have been far better off without the operation. I may cite one case in particular, that had been diagnosed cystic disease of both ovaries, but on opening the abdomen and close examination the cystic disease failed to show up. The operator, however, thought it best to remove the ovaries lest the disease should show up later on. Now, this simply shows how a thing may be run into the ground by the sheer craze for reputation. There were some fifteen or more other general practitioners who witnessed this operation with me, and it was interesting to see the exchange of frowns from one to the other during the later part of the operation. The skilled professor tried very hard to justify his theory for castrating this poor woman, but it failed to have the desired effect upon those who were present. The

main symptom complained of by this woman was pain in the region of both ovaries at each menstrual period, with some irregularity of her menses. I claim that such cases can be relieved, if not cured, by medicines and electricity. Dysmenorrhea with narrowing of the internal os of the uterus can be successfully treated by three applications of Goodell's uterine dilator, followed each time with six minutes intra-uterine electricity by the faradic battery. I have never failed to cure a single case where this treatment was adopted.

I was very favorably impressed with the remark made by Prof. Bangs of the Chicago Policlinic, in one of his lectures on gynecology, when he said, "that after some fifteen years of active practice in his *special* branch, he had come to the conclusion that three-fourths of the diseases that women suffer from were due to constipation of the bowels." He also remarked in one of his lectures on cervical lacerations, "that three-fourths of these lacerations were almost harmless, and hence did not require operative procedures and that conservative treatment yielded far better results in such cases."

Thus we see, there is much for the general practitioner to consider before allowing his female patients to go off to be treated by the city specialist. There is no plausible reason why the general practitioner should not do as good work and get as good result in the majority of such cases, provided he has as well equipped an office as the city surgeon or specialist. In doing this he not only saves his reputation from being at the disposal of the criticising city specialist, but of equal import he saves hundreds of dollars that would otherwise leave his own needy pockets for those of the specialist. There is no reason why the general practitioner should not operate for cataract, or perform iridectomy, or remove a nasal polypus, or do any other work that he is called upon to do in the science of surgery and medicine, provided he keeps abreast of the times and is properly equipped for his work. He should consider that the city specialist's opportunities for acquiring knowledge are just the same as those of the general practitioner, for both sit side by side in the lecture hall, and hear the same lectures and witness the same operations in the same amphitheaters. It is no less the priviledge of the general practitioner to take special courses at the post-graduate schools at the great medical centers, than it is the privilege of the specialists. And just here let me add, there are many who call themselves "specialists" who have taken up their *specialty* without taking a regular course in the science of medicine, thus leaving out the real ground-work of their specialty. Such men should not bear the title of doctor. They are not prepared to do their work near as well as the general practitioner. Some of your readers may infer from what I have written that I mean to cry down the specialists. I simply desire to elevate the general practitioner and place him just where he rightly belongs, regardless of the claims of the specialist. It is true, we have some very worthy and distinguished specialists, and far be it from me to detract one iota from their escutcheons. All honor and praise to such men as Chisolm, Munde and McGuire, all of whom were once general practitioners, and well grounded in the science of medicine before they became specialists. We need more such liberal minded men in our professio n to absorb the many mushroom specialist who are constantly springing up over the country.—*Jour. A. M. A.*

---

**Me and the Cat.**

RICHARD X—— is an incorrigible youngster of ten who has shown a tendency to lay the blame of his misdeeds on other shoulders. His favorite scapegoat was the family feline. A jar of sweets could not be opened, or a bit of gingerbread purloined, or a vase broken to atoms, without a lame excuse of Dick's, "I guess it was the cat," calling forth his mother's reproaches:

"Richard, you must not lay the blame on the cat of all the wickedness you are guilty of in this house."

Not long after one of these upbraidings, in Sunday-school, his teacher asked Richard the question, apropos of the devil's power on earth.

"Who is responsible for the wickedness of this world?"

It was with a mixture of a contrite spirit and the old habit that little Dick answered: "Well, I suppose that I'm partly to blame. But—but I think our cat has her paw in it."—From the "Editor's Drawer," in *Harper's Magazine* for February.

# SOCIETY REPORTS.

## THE LOUISVILLE CLINICAL SOCIETY.

*October 10, 1893.*

### OPERATION FOR APPENDICITIS.

DR. A. M. VANCE: This specimen is an appendix vermiformis removed this morning from a patient whom I saw for the first time just before the meeting of the Surgical Society last night, having been referred to me by Dr. Trunnell, who was called and made the diagnosis just before I saw the case. The man æt. twenty years, had been treated as I understand six days for typhoid fever. It was a very rapid case; there was a large mass in the right iliac fossa; patient having been taken suddenly sick a week ago, having suffered pain all the time; with loss of appetite, and nausea whenever he attempted to take food. McBurney's point was very well marked. There was no evidence of general peritonitis; there had been very little fever according to the history I was able to elicit from the family. His pulse was 90 and temperature 100 F. when he arrived at the Infirmary. I operated this morning evacuating probably 1½ pints of pus and along with it a number of fecal casts. I show you in this vial three which have been dried out. I found the appendix covered by very much inflamed and adherent omentum, the appendix being gangrenous as was also its mesentery, which was extensive. I removed the appendix with a large piece of omentum packed the cavity with gauze around a glass tube. The patient is doing well.

#### DISCUSSION

DR. W. H. WATHEN: When you opened the cavity and removed these structures did you expose the intestines freely?

DR. A. M. VANCE: No, I simply opened the abscess cavity. The peritoneal cavity was shut off completely by adhesions of the great omentum to the parietal peritoneum. I stripped up the appendix to its attachment to the cæcum and tied it off in the cavity of the abscess, did not enter the peritoneal cavity proper at all.

### DEATH RESULTINC FROM A VERY SMALL CALCULUS IN THE BLADDER.

No. 2.—A month or so ago I was called by Mr. Morris to see a child eighteen months old, with a history that three days before he had been called on account of obstruction in passage of the urine; he had endeavored to catheterize the patient, but the catheter would not go in; finally, however, he passed a solid sound and the bladder was emptied by the side of the sound. The next day when he visited the patient the bladder was again full. It was there he noticed that the scrotum had become tremendously distended and he thought the trouble might possibly be hydrocele. In consultation with some of his colleagues he tapped one side, but drew off nothing except a few drops of water. At the end of the third day I was called and told him that I could not understand what caused obstruction unless it was the impaction of a stone. I had a very small lithotomy staff with me which I introduced and at once touched a stone. The child was in a very extreme condition and was uremic. I took away the tremendously distended prepuce so as to get at the urethra better and made an incision in either side of the scrotum, the bladder having been emptied by the passage of the staff. (The child died of uremic poisoning twelve hours afterward). After the incisions were made in the scrotum it was emptied of the fluid by pressure. Dr. Baker made a post-mortem and found this little stone outside of the urethra in the scrotal tissue about the deeper portion of the urethra.

It is an interesting specimen and caused the death of the child.

### AN EPICYSTOMY.

DR. I. N. BLOOM: A young man then seventeen years of age, on the fourth of July, two years ago, while celebrating the day in a perfectly natural way without excesses of any kind, fell astradle a fence. After about two or three hours he passed blood from the urethra; this micturition of blood continued for two wesks, then ceased. At the end of that time he was attacked with all the signs and characteristic pains of ordinary cystitis, He consulted a physician, who made the diagnosis of cystitis and treated the patient for quite two years. During that time the bladder was washed out at least once a day. The patient grew worse and the washings was discontinued; he was better during the intervals and worse when treated.

When he came to me, in July, he was suffering from high fever—temperature 102° to 103° F., with an extremely rapid pulse. He was then nineteen years old. He had never had intercourse; never had venereal trouble of any kind and gave a clear history. I felt satisfied that the case was one of secondary cystitis, and that in any event an operation would be justifiable. I consulted with Dr. Griffiths, who fully concurred in my views The fever went down in ten or twelve days, but the pulse continued very rapid—110 to 120 to the minute. I sent him to the St. Joseph infirmary, where he was treated four

or five days to get him into good shape for the operation. There was no more fever than could be accounted for by severe cystitis. I had examined his urine, found specific gravity 1018; pus, not a very large amount; sufficient albumen to be accounted for by the pus only, and, after a hasty microscopical examination, nothing indicating further trouble.

On the fourteenth of August, assisted by Dr. W. O. Roberts, I performed the operation of epicystotomy in the usual way, i. e., with an air bag (I would have preferred a water bag, but there was none at hand) in the rectum and the bladder distended with ten ounces of water. The operation was concluded without any trouble, the peritoneum not being the least in the way, and I removed from the bladder a large phosphatic stone 1½ ounces.

The boy did very well for a week, except that at no time, during the week, did he have any appetite, and with difficulty could he be persuaded to drink two or three glasses of milk; all other food was absolutely abhorrent to him, and he was supported mainly on wine. The peculiar part of it was that alalthough the temperature never went above 100F., the pulse never varied from 110 to 115, and 118 to the minute. I packed the wound with idoform gauze; used no sutures. On the second day I took out the gauze. For the first week the urine was voided in part through the urethra, and in part through the wound; at the end of the week very little came through the wound. On the eight day there was a slight slough in the wound. Although I did not consider it sufficient to be of any importance, I called Dr. Robert's in consultation, and he agreed with me. Ten days passed in this condition, pulse, and temperature remaining as stated. His abdomen at at no time was tympanitic, he had no chill, and altogether the case was a very puzzling one. Then the temperature became subnormal, 97.5°F. in the morning, not going higher than 98° and sometimes not higher than 99°F. in the evening. This was the condition of affairs until the boy died on the fifteenth day after the operation. Toward the end of the last four or five days, he almost ceased passing any urine by the urethra, all of it coming out at the abdominal wound.

It is my opinion that this patient died of pyelitis.

### DISCUSSION.

DR. A. M. VANCE: Did the patient become comatose before death.

DR. I. N. BLOOM: No, I saw him in the morning before he died. Death occurring in the afternoon. He was perfectly conscious up to the time of his death. I will state that the stone removed from the bladder of this patient, and which I have exhibited here tonight, weighs 1½ ounces. I had no opportunity for a post mortem.

DR. J. M. MATHEWS: About what quanity of urine was secreted each day after the operation?

DR. I. N. BLOOM: The urine would soak through the bandages, and there really was no way of estimating the quantity.

DR. A. M. VANCE: It seems to me that if this patient had suffered from any active inflammatory trouble, there would have been some rise in temperature.

DR. I. N. BLOOM: The temperature was at one time 101° F, never going any higher. The pulse was always high, between 110 and 120, the first ten days, and for the last five days between 120 and 140. Lack of appetite was characteristic from the first.

DR. T. P. SATTERWHITE: Is not continuous high pulse always indicative of peritoneal trouble?

DR. I. N. BLOOM: You can have peritoneal trouble with low temperature and high pulse, but you would expect some tympanitic condition of the abdomen, which was entirely absent in this case.

DR. W. L. RODMAN (Visiting): I think Dr. Bloom's explanation of the case is the correct one, I do not believe the patient died of peritonitis. I do not think you would expect to have peritonitis as late as the fifteenth day after the operation. I have never heard of such a case, and believe that peritonitis is often clearly shut out. I think the patient died of pyelitis and suppression of urine.

DR. W. H. WATHEN: If this be true, why were not there some mental disturbance manifest in the case?

DR. W. L. RODAM: I have seen suppression of urine with no disturbances of the mental faculties at all until very shortly before the end. I have seen cases where there was no urine at all scarcely with the patient's mental faculties perfectly clear until a very few hours of the end—in strangulated hernia for instance.

DR. W. H. WATHEN: Was there any change immediately after the operation?

DR. I. N. BLOOM: The change in two days was quite marked; there was an improvement in the patient's condition, the fever was reduced, but the pulse remained very high.

DR. W. H. WATHEN: It is impossible that the immediate cause of death was pyelitis, but I cannot think that there was suppression of urine otherwise there would probably have been more mental disturbance. I am sure that peritonitis was not a factor, because there could not have been sufficient peritonitis to cause trouble without evidences of it—distension of the abdomen and other characteristic symptoms. Still there may have been septic infection after labor where there was no distension of the abdomen simply a general infection destroying the vital functions, such as there may possibly have been in the case under discussion.

DISCUSSION.

Of a paper read by Dr. I. N. Bloom,

"SOME POINTS ON CHANCROIDS"

DR. J. M. MATHEWS: I cannot conceive of a subject of more importance to any Medical Society than that of syphilis. It is of value to have such a learned syphilographer speak to us as has been the case to-night. There is no general practitioner of medicine, no surgeon and no specialist who does not meet with this disease in some form. It is a terror to the profession. Just as I was starting from my office to attend the meeting of this Society, one of our business men came to me and said he wanted to ask concerning his brothér-in-law, who happens to be a young man twenty four years of age now in a very responsible position in business. I had to say to him that I believed the gentleman in question was not only seriously affected, but that he conld never recover. My reason for saying this was that he has syphilis of the rectum. I am sorry the essaylist did not reach that point. and tell us how to best treat syphilis. But whatever the mode of treatment, or its application, I am at least forced to believe that when this terrible disease does effect the rectum, it is incurable. I scarcely wish to qualify that assertion. I know some men believe that when syphilitic ulceration exists in the rectum, by proper antisyphilitic medication it will disappear. I have taken the position that if the trouble is syphilitic and is attended by stricture, it is just as incurable as cancer. I have never seen an ulcerated syphilitic rectum cured. Therefore in my special line I regard it in the same light that we do cancer of the rectum an incurable affection; the only difference between the two being that syphilis takes a long time to kills cancer kill, more quickly. It is to the advantage of the patient to have the latter. This is a subject in which we are all interested; the specialist of whatever kind meets syphilis in his special line, and I hope the essayist will in closing the discussion tell us how to cure it, if syphilis is curable. I mean, of course, his general plan of treatment.

DR. W. L. RODMAN: I was not prepared to believe until this evening that syphilis was so much on the increase and chancroid on the decline; though in thinking over the subject it does occur to me that I have seen in recent years more cases of syphilis and fewer of chancroid.

As to the etiology of chancroid—I must confess that I have never seen my way clear to accept the new theory that chancroid is due to simple pyogenic micro-organisms; I am constrained to believe that there is something specific about the chancroidal virus. I know that this theory is gaining more or less acceptance by the profession, but it seems to me that there are strong reasons for adhering to the old doctrine that there is something specific about the virus of chancroids. There are certain features which are difficult of explanation in any other way. I admit that no special germ has ever been found, but that is hardly a potent argument against the fact that one may be present. I have never seen for instance enlarged glands coming on as a result of suppuration say in the axilla from an abscess of the arm or the pectoral wall. I do not think we can get inoculation from ordinary healthy pus. I believe that there must be something specific in the pus that comes from chancroids.

DR. A. M. VANCE: Of course a great many cases of the character under discussion come under my observation, but I have not kept a record sufficiently accurate to be able to give any data on the subject.

DR. GEO. W. GRIFFTHS: I have seen more cases of chancroid than I have of chancre in the last year.

DR. W. O. ROBERTS: I am convinced that chancre is more common than chancroid I think that a great many of the cases of so-called chancroid we see in the hospital and in the clinics are really chancre. We do not follow the cases up long enough to be able to say positively. I know that several times I have missed the diagnosis, and have been corrected by the appearance of secondary manifestations later. As you know secondary manifestations do not always come on in a certain stated time; it may be three weeks, three months or six months. Then again it may be so slight as to hardly attract attention.

In reference to the specific virus of chancroids: Like Dr. Rodman I believe that there is something else besides pyogenic micro-organisms.

DR. I. N. BLOOM: All those who claim to have found the pathogenic bacilli of chancroidal virus, have failed to find anything but pyogenic germs in pus from the body of the gland or in the bubo resulting from it. This is quite contrary to the rule, but it is a fact that each investigator—and there have been eight or ten—who claims to have found the specific bacillus of chancroid, makes the further statement that he has been unable to discover it in the bubo. Is it your belief that specific chancroid is the cause of a simple bubo, *i. e.*, not specific in nature? Or do you believe that if there is a bacillus that is not a pyogenic micro-organism which is the cause of chancroid, it also exists and has not been found in the bubo?

DR. W. L. RODMAN: Pus from a bubo is just as inocculable as pus from a primary lesion, and if there be a specific germ in a primary sore, then that germ should be found in pus from a bubo.

DR. I. N. BLOOM: Pus from acne will produce the same sort of a sore by inoculation.

It is claimed by some, for instance, that after a time the pyogenic micro-organisms disappear from repeated inoculations of the virus of chancroid, but that the sores can be perpetuated endlessly. This claim is disputed by those who have made experiments; what one side claims the other side attempts to disprove. The premises are not granted by both sides. I think the question is still subjudice.

DR. W. O. ROBERTS: Do you believe that the gonococcus is ever found except in gonorrhœal pus?

DR. I. N. BLOOM: It is declared that it is not found in gonorrhœal rheumatism, but to the best of my knowledge and belief it is found in suppurative bubo. Whether the gonococcus is the pathogenic germ of gonorrhœa, I am not prepared to state. I would like to have Dr. Frank express his opinion upon this subject.

DR. LOUIS FRANK (Visiting): It is conceded by all authorities, far as I have read, that the gonococcus is positively the cause of gonorrhœa. The gonococcus is not only found in gonorrhœal urethritis, but it is found in gonorrhœal buboes; also it has been discovered in the rectum of patients who had ulcerations and were supposed to have been infected by the gonorrhœal virus; my remembrance is that it has also been found in sores where infection has been supposed to have occurred, and in gonorrhœal joints. I have not seen anything to the contrary.

DR. A. M. VANCE: I believe that later investigators do not agree that the gonococcus causes the so-called gonorrhœal rheumatism. The idea prevailing is that gonorrhœal rheumatism is a joint disease the result of sepsis, just as in the fever following child birth we have a pyemic condition.

---

Dr. Wathen reported

THREE SUCCESSFUL CASES OF VAGINAL HYSTERECTOMY.

(See page 201).

DISCUSSION.

DR. J. M. MATHEWS: I would like to ask Dr. Wathen the ages of the three patients referred to.

DR. W. H. WATHEN: The age of the first woman was forty-four years; the age of the second about forty-eight years; the age of the last thirty-three years. Dr. Louis Frank assisted me in these operations. Dr. Rodman was present at each of them, and Dr. Satterwhite was present at the last one.

DR. W. O. ROBERTS: Did you remove the appendages?

DR. W. H. WATHEN: I removed one of the appendages in the first case. In the second case I did not remove the appendages, because the broad ligaments were tense and the ovaries were held out so far they could not be included in the clamps and so it was not necessary to continue the operation further in order to remove them. In the last case I removed the ovary and tube from one side. The other was high up so I left it.

DR. W. O. ROBERTS: I would like to ask Dr. Wathen why he prefers vaginal to abdominal hysterectomy.

DR. W. H. WATHEN: Vaginal hysterectomy is much easier than abdominal hysterectomy and results have been far more favorable. In the practice of an expert operator who observes everything in the interest of the patient, the mortality should not exceed five to ten per cent. The operations for cancerous disease performed several years ago, show an immediate mortality of nearly twenty-five per cent, and the permanent results were not nearly so favorable as in the operations by the vaginal method. But this would be very much changed now; the mortality in abdominal hysterectomy would not be so great as formerly because we now cleanse the vagina and uterus and by curettage, remove all danger of sepsis from that source; we place the patient in the Trendelenberg position and can ligate the broad ligaments ovaries, etc, much better than we could previously. It is probable that the immediate mortality from abdominal hysterectomy would now be very low. I have a patient under observation upon whom I shall probably do an abdominal hysterectomy, Some six months ago I curetted her thoroughly and removed a great deal of cancerous tissue from the body of the uterus, the neck being apparently healthy, The tissue removed was examined microscopically by Dr. Frank, and I believe also by Dr. Vissman, and the trouble pronounced unquestionably carcinoma. The uterus was found to be twice its normal size, and the vagina very small, the patient being a maiden lady of fifty-two years, I requested that she report to me when there was a recurrence of the trouble. About three months after she returned home she married a "rich old widower," and has had no symptoms of cancer since, but she will have a recurrence of the growth, and if she returns to me I shall do an abdominal hysterectomy because the uterus cannot be removed through the vagina.

DR. A. M. VANCE: What do you think of the operation of scacral section?

DR. W. H. WATHEM; That operation has been made prominent by Dr. Montgomery, of Philadelphia. I have read everything he has written upon the subject and have talked with him about it. While he deserves praise for his courage in this work, I see no real necessity for the operation. I would much prefer, if the vagina is too small to remove the uterus through that channel, to preform an abdominal hysterectomy.

# THE LIBRARY TABLE.

## BOOK REVIEWS.

*On Gout,* as Peripheral Neurosis. By Willoughby Frances Wade, Fellow of the Royal College of Physicians, etc.; Consulting Physician to the General Hospital, Birmingham. London, Simpkin, Marshall, Hamilton, Kent & Co. Limited. Birmingham, Cornish Brothers, New Street, 1893.

In this little book of fifty-nine pages, the author refers to the three theories current in regard to gout; namely, the humoral theory, the neural or nerve theory, and the neuro-humoral theory, and expresses the conviction that the latter accounts for more of the phenomena of this disease than any other. The frequency with which the joint of the great toe is attacked, as well as some other isolated facts, is cleverly explained, and the whole essay is an interesting addition to the literature of this important disease.

*Traite des Retrecissements de l'Urethre,* par le Dr. P.. Harmonic, etc., etc, with a preface by Prof. Tillaux and 107 cuts in the text. 625 pp., Octave Doin, publisher, Paris, 1893.

Among the functions which are absolutely necessary to the physicial health of man that of the kidneys and their appendages easily take a place in the front rank. Strictures of the urethra, in forming an obstacle to emission of the urine, are capable of producing a great amount of suffering and even death itself. Hence it is by no means astonishing that the attention of surgeons, of all times, has been directed towards the treatment of this serious conditon. An enormous number of works have been written on this subject, and, it is far from being exhausted. This publication, is, without doubt, the most important, and, at the same time the most complete, which has been offered to the medical profession on this subject. It is warmly recommended by the well-known Prof. Tillaux, of Paris, who has honored it with an extensive preface. The work is divided into three parts, the description of urethral strictures, their complications and treatment.

The first section, occupying one hundred and eighty-seven pages after a preliminary definition, goes deeply into the consideration of the etiology. Gonorrhœa is the most frequent cause on account of its chronicity favoring the formation of cicatricial tissue. Besides urethral gummata and congenital strictures, they are of either inflammatory, cicatricial or a mixed origin. The clinical course and symptoms, examination of the patient, measurements of the urethra and the requisite instruments and principles, the various varieties in man as well as in women, together with the pathology, a dignosis and prognosis are fully considered. The portion relating to the complications covers four hundred and three pages and deals very completely with all the details of our knowledge referring to them. The third section considers their treatment, it being quite exclusively and properly surgical. It fills one hundred and eighteen pages. It is a practical work and shows the results of careful study and experience. It may be recommended to those desiring a special work on this subject, for it neglects no detail but treats all fully.

*Etude Sur le Dermographieme ou Dermoneurose Toxivasomotrice,* par Toussant Barthelemy, Medecin nomme au concours de Saint-Lazare, etc. With seventeen cuts in the text. 287pp. Societe des Editions Scientifiques, 1893.

Under this title, dermographism, the writer has studied a condition in which the skin presents the peculiar power of retaining inscriptions written on the surface with any blunt instrument. This sensitiveness of the integument may be so great that various dermatoses, as for example infectious diseases, may be simulated and give rise to errors in diagnosis. It is a special state of the vasomotor nerves, in a specially susceptible nervous system, which is impressionable or impressed either by heredity or by acquirement, due to the influence of the toxic agent, acting on the vaso-motor nerves, either peripherally or centrally. He first studies and examines the influence of heredity, social conditions, etc., in its causation, its pathogeny, its relation to allied states as blushing, spontaneous ecchymoses, hemorrhages, etc. By means of electricity he had succeeded, with electric currents of high tension, in producing experimentally a state very closely resembling dermographism. Its diagnosis is quite easy, though it is freqgently passed over unperceived. It is only necessary to mark with any blunt instrument, the finger-nail, the end of a pen-holder, etc., on the skin of a susceptible subject, in order to observe the skin rise up in relief over the track of pressure and retain the impression more or less distinctly, for a longer or shorter time. It is a vaso-motor disturbance, without pruritus, sensation of heat, anesthesia or hyperesthesia, as in urticaria. Its practical importance may be at once seen, in that in certain forms, various cutaneous affections may be simulated. As remarked before, it is an associated symptom of the nervous diathesis and arthritism. The work is divided into two parts. In the first he considers fully the various details of our knowledge of this subject. The second contains the records of the cases which he has observed and collected, among which there is a large amount of interesting historical matter on the relation of this affection to witchcraft and trials for sorcery where the so-called impression of Satan's hand, etc., was remarked. It is a very interesting work on a subject quite unknown.

*Manley on Hernia.*

This work contains the fullest accounts of all the ancient and modern operations in hernia; besides, clearly sets forth those hygienic and palliative modes of treatment, by which many varieties of hernia may be cured in early life.

Price reduced from $3 to $2.00 (post free). Published by the Medical Press Co. Limited, 1725 Arch street, Philadelphia, Pa.

---

*The Review of Reviews*

for February is strong in all of its departments. In the "Progress of the World" the important political, social and industrial events of the month are reviewed and their significance clearly and frankly set forth. This department alone contains fifty timely illustrations, chiefly portraits of well-known men and women. Among the portraits are those of President Dole and his cabinet and sketches, drawn from life, of Representatives William L. Wilson, of West Virginia; Chas. F. Crisp, of Georgia; Thomas B. Reed, of Maine; Benton McMillan, of Tennessee; Thomas L. Johnson, of Ohio, and Julius C. Burrows, of Michigan. Apropos of the opening of the Manchester Ship Canal, the editor discusses that and various other waterway projects which are being considered by European governments.

---

*February "Cosmopolitan."*

The secret of the great success of *The Cosmopolitan* is not so hard to find, if one looks carefully over the number for February. A story by Valdes, the famous Spanish novelist, the first from his pen to appear in any American magazine, is begun in this number. Arthur Sherburne Hardy's story, "A Rejected Manuscript," is charmingly illustrated by L. Marold, who we believe makes his first appearance in the magazines on this side of the water. A profusely illustrated article on the designing and building of a war-ship appeals to the interest taken by all in the new navy, and a thrilling description of a naval combat under the significant title: "The Meloban and the Pentheroy" describes, after the manner of the Battle of Dorking, a possible sea-fight, the outcome of which is watched by the entire naval world. "Gliding Flight" is an interesting contribution to the problem of aerial navigation by one who has studied the fight of soaring birds in the East for twenty years. Elaine Goodale, who married a member of the Sioux nation, has some interesting information of Indian Wars and Warriors. T. C. Crawford, the Washington correspondent, gives the first half of a startling story, under the title of "The Disappearance Syndicate." The poetry in this number by Sir Edwin Arnold, Graham R. Tomson and William Young, is unsually good. The departments, "In the World of Art and Letters" and the "Progress of Science" continue to have as contributors men famous in both continents.

---

*The February Number of Godey's Magazine*

appears in a new and most attractive cover, and with many innovations and improvements in the inside of the *Magazine*. In every respect this number is the most attractive ever issued by the Godey Publishing Company. It has a choice and varied contents, the opening article, "How to Make Money in Wall Street," being from the pen of Henry Clews. There are the opening chapters of a novel, "This Man and This Woman," by Margaret Lee, with illustrations by Paul Nimmo Moran; a short story, "The World's Gain," by Henry Milford Steele; "Superstitions of the English Miner," by S. P. Cadman; "Feroline," short story, by Lucy C. Lillie; "The Valley of Roses," by Prof. A. L. Rawson; "The Royalty of Hawaii," by Herbet Stanely Renton; "American Women in Mexico," by Marie Robinson Wright; "A Tragedy Pro-Tem," short story, by James Clarence Harvey; "A Begging Letter," a farce, by Anna Robeson Brown, with short sketches, numerous illustrations, and poems by Louise Chandler Moulton, Clinton Scollard, Richard Burton, Henry Tyrrell, Marie Frances Upton, A. L. Donaldson and others. Florence Hull conducts the Home Department, Stella G. Florence's name appears as fashion editor, and there is a new department for Our Boys which ought to attract universal attention.

---

**Flint (A.) on Treatment of Fermentative Dyspepsia with Subgallate of Bismuth.**

Dr. Flint states that in nearly every case of functional dyspepsia under his observation within the last ten months he began treatmeant by giving five grains of bismuth subgallate, either before or after meals. In some cases it seems to act more favorably when given before meals, and in others its action is better if taken after eating. Salicin he has often found to prove satisfactory. The proportion of unsuccessful cases was about twenty-five per cent., but in some cases the effects of this remedy when given alone have been remarkable. The bismuth subgallate, however, is almost a specific in cases of purely functional dyspepsia with flatulence. He has used bismuth subgallate since December 8, 1892, and reports but two cases where no relief was noticed. Both of these cases were in hysterical women. He first used the remedy in a case of dyspepsia of eleven, years' standing with excellent results.

The following are a few of the cases of remarkably prompt and favorable action; A case of alcoholism of twenty years' standing, with habitual dyspepsia for the last five or six years; bismuth subgallate gave almost instant relief. The flatulence and distress disappeared in twenty-four hours, and did not return, except in a very mild degree, when they were usually relieved by a single dose. A case of dyspepsia of four's standing, with with a chronic diarrhœa, was entirely cured in five days by the use of subgallate of bismuth alone. In this case, the trouble returns every few weeks and is relieved by two or three doses. He prescribes it in the tablet form, each containing five grains.

During the treatment of the cases patients are simply directed to avoid excesses in food and drink, and to eat little or no pastry or sweets.—*N. Y. Med. Jour.*

# CURRENT LITERATURE REVIEWED.

IN CHARGE OF ELLISTON J. MORRIS, M. D.

## THE BUFFALO MEDICAL AND SURGICAL JOURNAL

for February.

An editorial on Symphyseotomy gives a short history of the operation, states that it has been employed during the past year by nearly every obstetric surgeon in the larger cities of America, and concludes; that while it cannot displace Cæsarean section in cases of extreme pelvic deformity, yet it may do so in cases with a useful diameter between six and seven and five-tenths centimeters.

The operation is described, and declared more easy, but probably not less dangerous, than Cæsarean section, and to be performed only by skilled surgeons. No reason, except easy performance, is advanced for preferring it to section.

A Letter from Mr. Lawson Tait criticises a paper by Dr. F. Byron Robinson, under the title

**What Kills After Laparotomy, Anæsthetic, Nephritis, or Infection'?**

Except for incisions in the flank the term laparotomy is objected to.

The author describes his discovery that ether stops, during its administration, the secretion of urine; while chloroform has not such action. Renal and pulmonary lesions, he says, leading to death, may be due to the use of ether.

Degenerative kidney changes are a frequent accompaniment of abdominal tumors of all kinds; but even when known to be present do not prevent his operating, but cause him to use chloroform. Cases are cited confirming his stand.

He does not think experiments on animals sufficient ground for treatment of human beings, and shows how the public sentiment, combined with the different inquest laws of England and Scotland, lead to the use of ether in the former and chloroform in the latter country.

He now uses, and so far with perfect satisfaction, a mixture of chloroform and ether, varying from one-third chloroform in the young to two-thirds for those forty years of age, or more. He calls this "ether mixture" and follows rigidly Simpson's directions for administering anæsthetics.

Dr. Marcell Hartwig read before the Buffalo Academy of Medicine a paper on

**Prostatic Disease With Special Reference to the Prostate of Old Age.**

He states that in spite of modern methods, operation for prostatic hypertrophy has resulted in very little benefit in most cases, and then, claiming little personal experience, gives a synopsis of the treatment of various authorities, and decides that so long as a man can completely empty the bladder by a catheter, operation is not called for; but as soon as he leaves some residual urine, an operation is necessary or cystitis, uræmia, and finally, death will result.

Supra-pubic cystotomy seems to be the choice of the author, but he is by no means enthusiastic in recommending it. The experiments of Dr. White are mentioned as proving the fact that atrophy of the prostate follows castration, or ligation of the vasa deferentia.

A very interesting discussion followed, in which most of the participants seemed to regard supra-pubic cystotomy advisable without delay, when cystitis threatened, or it became impossible to completely evacuate with a catheter.

Some of the speakers had operated successfully and a case was cited where a hard rubber tube was subsequently worn for several years, giving great comfort.

In regard to the opinion of Dr. White, doubt was expressed whether castration or ligation of the vasa deferentia would give relief to those elderly men to whom the testes were almost, or quite, inactive; as it was very improbable that any one would permit such interference at an early date, before the pain and obstruction became severe.

The prompt effect of a twenty per cent solution of antipyrin in stopping hemorrhage from the bladder was mentioned. Its use had been suggested by its known effect in epistaxis, etc.

The remaining paper, by Dr. W. A. Crockett, is entitled

**Observations on the Results of Removal of Diseased Uterine Appendages.**

Accompanying the paper is a table of thirty cases, showing the reason for operating and the condition before and after each operation.

The author does not claim to cure every case in the sense of completely rejuvenating her, and leaving her without ache or pain, and complains of those opposed to the operation denouncing it because this is not done. No other surgical procedure, he says, is subjected to such a test. His results have been good, though, and the symptoms complained of relieved.

The causes preventing perfect cure he classes under the following heads:

Ventral hernia, which is apt to follow in cases where a drainage tube is used.

Lack of skill and judgment on the part of the operator.

Neglect of treating all the disease. The author thinks endometritis exists in every case of salpingitis, and every uterus should be curetted before excising the tubes and ovaries. Every displaced uterus should be replaced.

The impossibility of leaving the pelvis in absolutely normal condition. Where raw surfaces are left, there will be some adhesions.

Affection of other organs, dependent or independent of disease of the pelvis. The ultimate results of this operation are influenced very largely by the effect of long standing tubal disease on other

organs, particularly the nervous system. When refractive troubles in the eye are corrected by glasses, the headache, due to them, does not instantly disappear, and a similar condition exists here, the focus of irritation is removed, but its effects pass away slowly.

Effect of long suffering and treatment on the patient's morale. The patient becomes morose and has a habit of magnifying every ache or slight pain; which makes her statements worthless.

Patient's subsequent occupation and condition of life: Many follow occupations which would be exhausting to a perfectly healthy person.

Besides having seen little good result from electricity, the author states that none of his patients could afford the tedious six months' or year's treatment which electricians require. The author sums his argument as follows:

Each case must be judged on its own merits and surrounding circumstances. There is no one form of treatment which will guarantee a cure.

Salpingo-oophorectomy stands on the same level as any other surgical procedure, and its results are influenced by a variety of elements which may play a part after any surgical method of treatment.

The results of salpingo-oophorectomy are sufficiently encouraging to justify its performance after milder methods have failed.

The most serious mistakes a physician can make are: (*a*) continuing local treatment after such a course has proven worthless; (*b*) making too positive assertions as to the favorable result of treatment.

---

THE CHARLOTTE MEDICAL JOURMAL

for January. Dr. J. Wellington Byers contributes a paper on

**The Antisepeptic or Rational Treatment of Typhoid Fever,**

advocating the use of calomel and the cold bath in the disease. His plan is to administer at the beginning of the attack small doses, sixth of a grain, of saccharated calomel, combined with bi-carbonate of soda, every hour till the bowels have been freely evacuated. This is repeated every day, or every other day, during the first ten days' sickness, as the indications demand, unless diarrhœa supervenes. when the remedy is suspended for a time. The author states that it is exceptionally rare to have a diarrhœa at this stage of the disease when calomel is emproyed in this way. Under this treatment he finds that the functions of the stomach are more properly performed. The tongue is clean and moist, there is absence of tympany, the secretions are open with perfect glandular action—a series of circumstances in which it is quite impossible to have diarrhœa. The author states also that there is no danger of salivation from its use in this way. It does not produce hypercatharsis, or does it induce asthenic conditions, as is generally believed. To the contrary it is a gentle and true tonic, which promotes activity of the mucous membranes and glandular organs, hastens the illimination of morbid substances in the tissues and circulation, and through these influences brings about a high state of cell activity, and the vital resistance of the entire organism is augmented. In addition to those general physiological actions it possesses antiseptic properties of undoubted value. The author is quite certain that it will lessen and prevent a large proportion of the pyrexia which usually accompanies this disease when treated by methods which fail to recognize and modify the seat of and cause of the fever. In the author's cases, ranging in ages from six to sixty years, the fever rarely reached a maximum of 103°, and when it did, it was in every instance promptly controlled by the exhibition of the remedy. The author believes that by the use of calomel in this way we avoid stupor and delirium, which are largely attributable to toxæmia, lessen the liability to the presence and inroads of the pus-producing cocci in the later stages, prevent ulceration and hemorrhage, and remove one of the most potent sources of death.

Dr. E. C. Boyte reports a case of "Superfœtation." The patient was delivered of a healthy female child at term and with the placenta was expelled a fœtus of three or three and one-half months, contained in a separate sac, which at the placenta margin seemed to be attached to that of the fully developed child by a substance resembling the gelatine of Wharton. The placenta and fœtus were in a healthy condition, and the circulation was independent, there being no anastomosis between the vessels.

Dr. Archer Atkinson contributes a paper on "Fistula in Ano," advocating the use of the elastic ligature in the treatment.

John J. Caldwell contributes a Review of Recent Electro-Therapeutics and Electro-Surgery. [Judging from the tone of the paper, electricity is the cure for all diseases. The author speaks of a new instrument, which he names the phonoplaint and which, when applied to any part of the body, will instantly indicate the condition thereof by certain sounds or movements. The author does not describe this wonderful instrument and states that "so far we have not deemed it best to present an illustration of my phonoplaint instrument."—ED.]

---

THE ANNALS OF GYNÆCOLOGY AND PÆDIATRY.

for January. Dr. Howard A. Kelley in a paper on

**The Diagnosis of Pelvic Inflammatory Diseases,**

presents the following conclusions:

(1) The history of the patient, associated with pain in the ovarian regions produced by deep abdominal or vaginal palpation, cannot *per se* establish a diagnosis of pelvic inflammatory disease.

2. An attempt to make a diagnosis without directly palpating the pelvic organs is at best but more or less clever guess-work.

3. The diagnosis can be made with certainty when resisting masses are felt choking the posterior half of the pelvis at the sides and behind the uterus.

4. It is possible in this way sometimes to mistake a retroflexed fundus, an extra-uterine pregnancy or a myoma, for inflammatory disease. This error on the part of the general practitioner, however, is in the right direction, calling for a more exact investigation or consultation with a specialist, and is therefore not detrimental to the patient.

5. For a more delicate appreciation of the exact condition of the pelvic organs, and in many cases in order to make any diagnosis at all, a bimanual examination by rectum and abdomen under anæsthesia is necessary.

6. The writer's trimanual method of examination by rectum, vagina and abdomen, is the most accurate of all, serving to detect the slightest irregularities of the uterus and ovaries, as well as the most delicate adhesions.

Dr. William Goodwell contributes a paper on

**The Effect of Castration on Woman,**

in which he states that his experience would lead him to the conclusion that, in the majority of the women who have been castrated, the sexual impulse, soon abates in intensity, much sooner than after a natural menopause, and that in many cases it wholly disappears.

He also believes that the death-rate from chronic diseases of the appenadages is greatly overrated, so much so that, in his opinion, more deaths result from the operation of removing the tubes and ovaries, in the hands of even the most successful gynæcologists, than from the disease itself. In his experience, after the patient has safely passed through the acute stage of the inflammatory attack, her life is in very little danger.

The life of a woman with one damaged appendage is in greater danger than the life of a woman with both her appendages diseased on account of the liability of the old inflammation being relighted by parturition. The author believes that a surgical operation is not always necessary to cure the ill-health of a woman whose appendages are diseased, and he goes further and asserts that even cases with all the subjective and objective symptoms of ovarian or tubal abscess have been cured by him by means of massage, electricity, local applications and general tonics. In a very few of these cases conception occurres. When driven to operation, the author advocates removal of the diseased side only, unless the menopause has been established already, or unless a good reason obtains for hastening it on. Should both ovaries be intrinsically diseased and their tubes contain pus, he would always remove both uterine appendages in their totality no matter what the age of the patient might be. When the pus is limited to the tube he would leave the ovary after breaking up all adhesions, or, at any rate he would leave some of the ovarian stroma in order to avoid the sexual changes resulting from the enforced menopause. Should the uterine appendages be merely adherent, and not intrinsically diseased to any extent, he would, as a rule, during active menstrul life, release them, and, perhaps, extirpate the worse of the two, but not both of them.

In regard to the removal of the appendages for the cure of insanity and epilepsy, if the insanity is limited to periodical outbreaks, strictly ovarian in their character, and with the menstrual flux as a storm center; if the epilepticits are preceded by an ovarian aura—that is to say, if they pivot around the monthly period, and appear at no other time—the removal of the appendages, by suppressing a pernicious menstruation, usually will bring about a cure in either disease. But when these organs are extirpated merely as a panacea *per se* for these disorders, irrespective of their ovarian origin, the operation affords no relief. The author is inclined to advocate the castration of the insane of both sexes for the prevention of the spread of insanity.

Dr. A. W. Johnston disscuses the

**Aetiology of Dermoids of the Ovary and Testicle.**

The conclusion which he arrives at are: First, that embryology is the proper field in which to study dermoids, and it is in the formation of the ovum itself, and not during its stage and in the manufacture of the individual, that we must expect to find this fault. Second, that no practical use has yet been made of the well-known fact that up to a certain point we are all protozoa, just as well as in the later stages we become amphibians and such like. Third, that it is in the study of this protozoic age that we must expect to find the seeds which result in the formation of dermoids. Fourth, that the author's studies accentuate the fact that a human being in its development passes through all the stages of animal life, from the lowest to the very highest, and that a failure to pass from one stage to the next highest is sure to leave its imprint in the shape of a pathological condition.

Dr. George S. Peck contributes a paper on

**Extra-uterine Pregnancy,**

reporting five cases. One case is of interest on account of the division of the lumen of the fallopian tube into three, one of which ends in a cul de sac, the other two coalescing further on. The pregnancy, however, took did not take place in the closed part of the tube. All five cases recovered, with the exception of the fifth who was in collapse when operated upon and died on the table in spite of the use of large doses of digitalis, whiskey and strychnia. The paper is illustrated by photographs of the specimens removed.

Dr. L. J. Hammond also reports a case of "Extra-uterine Pregnancy at three months."

Dr. W. J. Hunter Emory reports a case of "Floating Kidney—Nephropexy." The sutures were removed on the sixth day. Union by first intention thoroughout. Temperature never rose to 100°. Some months have now elapsed since the operation, and the kidney remains *in stiu*, the patient wonderfully improved in general health and doing general housework.

This issue of the journal also includes an abstract of a paper by Dr. A. Margen Cartledge, entitled "Is Operation Demanded in All Cases of Appendicitis not barred by surg-

ical limitation should be operated upon. The best time, provided the symptoms are not too urgent, is after the bowels have been thoroughly moved.

In the Department of Pædiatry Dr. Merrill Ricketts discusses

**Excision of the hip-joint in Tubercular Disease.**

The author, in regard to the reason for entering the joint, gives the following: First, acute suppuration, bony or synovial, origin due to any cause. Second, acute tubercular suppuration. Third, arthritis, non-suppurative, but generally occasioning great pain, or deformities by other means. In number one and two resection is the vital indication. Number three not so important; let alone except to walk orthopædically. Do not remove the head for simply synovial fluid or marginal ostitis, or osteomyelitis of head of bone, but in cocco-femoral articulations, involved by suppurations, the head should be removed.

The remaining article in this issue, "Surgical Shock" by Dr. Charles P. Noble, has already been published in THE MEDICAL AND SURGICAL REPORTER for January 20th, 1884, page 80.

# PERISCOPE.

## MEDICINE.

### Brannan (J. W.) on Quinsy and its Treatment by Early Incision.

The author's studies tend to confirm a fact which has long been accepted by most laryngologists, viz., that the operation of opening a peritonsillar abscess is attended with no danger if properly performed. They also emphasize the necessity of early evacuation of pus, lest ulceration of an adjacent artery may take place. He offers the following conclusions:

1. In quinsy, the inflammatory process is usually situated without, and not within, the tonsil. 2. If pus forms it should be evacuated at the earliest possible moment. 3. Unless there are signs of pointing elsewhere, the incision should be made through the soft palate directly backward. 4. If the tension of the parts is very great, the incision is indicated, even though pus has not formed. 5. If ordinary surgical care is exercised, there is no danger of wounding the internal carotid artery. 6. In cases of deep-seated inflammation, in which the pus comes to the surface slowly, erosion of the arteries in the neighborhood may take place. In such cases, therefore, we must be ready to deal with arterial hemorrhage at the moment the abscess discharges into the pharynx — *Med. Record.*

### Morrison (F. H.) on a New Physical Sign for the Early Diagnosis of Croupous Pneumonia.

In several cases recently seen where the general symptoms of pneumonia were present, but none of the ordinary physical signs, I have discovered what I am venturing to describe as a new physical sign. On careful auscultation of the chest I have heard jerky expiration over a limited area, and on noting the position of this area have found developed in it subsequently the usual signs of pneumonia. This jerky expiration is the first physical sign developed, and can be heard soon, if not immediately after, the rigor, before dullness or crepitations appear. It is much more distinct in children, but I have also heard it in adults. The following cases sufficiently illustrate what I wish to point out, though I have notes of several others: 1. A girl, aged four years, was first seen by me about 9 P. M. on April 29th of this year. Her mother stated that she was seized with a shivering fit about 12.30 P. M. on the 28th, having been previously quite well. Her hands were cold and she was drowsy and thirsty. There was pain in the limbs in the afternoon and her breathing was short. She became delirious about 9 P. M. When seen by me on the following day her breathing was very rapid. She had a slight cough and a very quick pulse. The temperature was 104° F. Except that expiration all over the right base was markedly jerky, nothing abnormal was found in the chest. On the 30th her temperature was 102°. The physical signs were the same. On May 1st there were slight dullness on percussion and fine crepitation over the right base. The pneumonia ran a normal course and the patient made a good recovery. 2. A young man, aged twenty, was first seen by me on April 3d of this year. He complained of pain in the right side and shortness of breath. On April 1st he became very heated whilst playing at football, and during the following night he had a rigor. His respiration was rapid, the pulse was quick, and the temperature was 103.4°. Except for jerky expiration at the right base posteriorly there was nothing abnormal on examination of the chest. Pneumonia was diagnosed at the right base. This was subsequently verified by ordinary physical signs. The disease ran a typical course, although convalescence was somewhat prolonged—*Lond. Lancet.*

### The Biological Treatment of Enteric Fever.

Though the principle upon which is based the treatment of certain diseases by means of the products of the vital activity of animal or vegetable organisms may seem dubious;

though, as with tuberculin, the subsequent outcome may be very disappointing and different from what had been hoped; though the explanation of the action may be wanting; though the result may seem chimerical, sufficient data have now accumulated to encourage investigation in this new field of therapeutics and to bespeak for it scientific consideration. The sixteen cases or more of tetanus reported as cured by the tetanotoxin, the many cases of myxœdema (and from recent reports some cases of psoriasis) said to have been vastly improved or cured by treatment with some preparation of the thyroid gland, the experimental and clinical work of the Klemperers and others with pneumonia, the work of Haffkine and others with cholera —all these afford some evidence of the practical value of the method, and encourage the hope that the principle upon which it is based may be applicable to many other diseases than those already named. We have already on several occasions discussed this subject in these columns, and have no wish to enlarge upon it now.

It is our present purpose to call attention to the valuable and reliable work of Eugene Frænkel and Th. Rumpf (*Deutsche Medicinische Wochenschrift*, 1893, No. 41, pp. 985, 987), at the New General Hospital of Hamburg, in connection with the treatment of enteric fever by means of sterilized bacilli of enteric fever and pyocyaneus-bacilli respectively, the report of which is couched in language at once conservative and assuring. The mode of procedure and the results in the two sets of observations were so nearly identical that we can speak of both together. Bouillon prepared from the thymus gland of the calf was inoculated with organisms of an ordinary degree of virulence and placed for three days in a thermostat kept at a temperature between 96.8° and 98.6°, and then sterilized by boiling for about twenty minutes in a water-bath at a temperature of 145.4°. Of this solution about eight minims (0.5 c. c.) were injected into the gluteal region as soon as the diagnosis was made. No noteworthy change was observed to follow, and upon the following day about sixteen minims (1 c. c.) of the fluid were injected into the other gluteal region.

This second injection was usually followed by slight elevation of temperature, sometimes attended with chilliness or a chill. On the third and on the fourth day a notable decline of the temperature was observed, together with free but not depressing diaphoresis. If at the end of this time the temperature manifested a tendency to rise, another injection of a larger quantity (2 c. c.) of fluid was given, and in this manner the treatment was continued, the dose being progressively increased.

In addition to the influence upon the pyrexia, the flow of urine was notably increased, diarrhœa was favorably influenced, and the general condition was improved. The result was the better the earlier the case came under observation. Complications and death were not invariably averted, nor relapses prevented, but the course of the attack was in most cases favorably modified and its duration distinctly shortened.

The results, on the whole, were eminently satisfactory. Of the thirty cases treated by Rumpf with cultures of dead pyocyaneus-bacilli, there were but three deaths. Frænkel promises to give at another time a detailed report of the fifty-seven cases treated by him with cultures of dead bacilli of enteric fever. Surely we cannot ignore the value and the importance of these observations, and the hope is certainly justified and the results recorded may be confirmed and extended by those of other observers. — *The American Lancet.*

### Diphtheria.

In *The New York Polychinc*, Dr. L. Emmett Holt writes substantially as follows on the subject of diphtheria:

In the treatment of diphtheria the first thing is isolation. The poison is given off particularly in the discharges from the nose and mouth, probably not from the breath. Handkerchiefs or towels should not be used for the nose, but absorbent cotten or bits of old muslin which can be burned immediately.

All the latest researches upon the subject of diphtheria point directly to the fact that the disease is first local, and afterwards constitutional. It is our duty then to attack the local disease on the tonsils energetically with the hope that the process may be arrested. Many plans have been suggested for this, such as Dr. Seibert's submembranous injections, the use of the galvano-cautery, and the local application of strong germicides, such as 1-250 bichloride, Monsel's solution, and hydrochloric acid. My own preference is for the last mentioned.

℞ Hydrochloric acid .....1 part
Glycerine.....2 parts

This is to be used as follows: A swab made by twisting absorbent cotten upon a splinter is saturated with the solution, but not so as to drip, and while the tongue is depressed, it is applied to the tonsils with a rotary motion. A second swab is to be used for the opposite side, and a fresh swab for each application, all being burned after using. This should be repeated in cases like the one before us once in four or six hours for the first day, afterwards once in six or eight hours for three or four days, while the disease tends to active spreading, and after that less frequently.

The advantages of the hydrochloric acid are that it is a powerful germicide, that it produces a good deal of disintegration of the membrane, that its effects are easily limited, and the sound parts are not unfavorably affected by it. We use the strong acid, and not the dilute form. When I began using it, I felt a little timid about using so strong a solution, having recently had a very extensive experience with it in a hospital epidemic, where during the past two months we have treated thirty-two cases. I believe we need have no hesitation in using so strong a germicide. A swab is always to be preferred to a brush for making such applications, since

with a brush the solution is likely to drip and injure adjacent parts.

In addition to these germicidal applications, and the earlier they are begun the more useful they are, the pharynx is to be kept clean by the hourly use of a gargle in children who are old enough to do this, or in younger infants by syringing the mouth, or swabbing with some weaker solution. For cleanliness we may use Dobell's solution, Seiler's solution, or bichloride 1-5000 containing ½ glycerine. These applications are not expected to do more than to keep the parts clean.

There is no call for nasal syringing in a case like the one before us. It is, however, to be begun in every case as soon as nasal discharge appears, whether there is visible membrane in the nostrils or not. This should be done with a small glass syringe, having a soft rubber tip, repeated every hour during the day, and every two hours during the night, without taking the child from his crib. Any of the three solutions mentioned above may be used for the nose. The addition of glycerine to the bichloride solution renders it less irritating.

What internal treatment shall we employ? None whatever excepting stimulants. We have no specifics for diphtheria, and after a through trial of most of the drugs recommended for use. I have abandoned them all, having become convinced that none of them have any special influence upon the course of the disease.

How soon shall stimulants be begun? This is a question which must be decided in each individual case. In some cases it must be begun on the first day; in others on the third day; in some not until the sixth day, and in some not at all. In diphtheria as in other diseases the best guide to the time for stimulation and to the amount of stimulants called for, is the patient's general condition and pulse. It is, I believe, a mistake to stimulate every case of diphtheria from the outset, in order to anticipate heart failure late in the disease. However plausible this may appear in theory, in practice I believe it to be very much inferior to the plan of withholding stimulants until they are indicated by the patient's pulse and the heart's action, when they should be pushed until the desired effect is produced.

For the swollen lymphatic glands no treatment is necessary unless they are very tender and painful, then use hot applications rather than cold. These glands rarely suppurate in diphtheria—never, I think, unless the process in the throat is one of a mixed infection.

There is one other means of treatment of which I wish to speak, although not called for in this case, and that is calomel fumigations in laryngeal diphtheria. This was first introduced by Corbin, of Brooklyn, and its very great value is now admitted by everyone in New York who has had opportunity to see them applied. Next to intubation I believe this to be the greatest advance in the treatment of diphtheria during recent years. Ten grains of calomel are vaporized over an alcohol lamp every two to four hours, the patient being kept in a close tent, made of sheets about his crib. This is to be begun as soon as laryngeal symptoms appear. In bad cases calomel fumigations may be used every hour. In the last epidemic to which I have referred three laryngeal cases, and two of them severe ones, were cured by this method without operation. In one of these I have reason to believe there was membrane in the trachea as well as in the larynx.

To summarize in a few words our treatment of diphtheria, the indications are:

(1) Germicidal treatment, preferably by the use of strong hydrochloric acid; used early to be effectual; especially valuable in cases beginning upon the tonsils.

(2) Local cleanliness by the free use of a weak antiseptic solution in the pharynx.

(3) Nasal syringing with the same solutions in every case where there is nasal discharge.

(4) Alcoholic stiumlants begun as soon as the first systemic effects of the poison are seen, and in very severe cases pushed to the point of tolerance.

(5) Calomel fumigations as soon as laryngeal symptoms appear.

(6) Intubation in laryngeal cases not relieved by fumigation.

## SURGERY.

### Operative Treatment of Peritoneal Tuberculosis.

The *Boston Medical Journal* says: The value of operation in the treatment of peritoneal tuberculosis in children has been much disputed and even yet is by no means generally allowed. The numerous cases benefited by laparotomy have been challenged as to correctness of diagnosis and the indications which were believed to predict a favorable result. The report of Conitzer* of seven cases operated upon for tuberculosis of the peritoneum throws some light upon the points in dispute.

The children varied from two and a quarter to nine years old. Four cases were of the exudative form in which there was a diffuse superficial inflammation of the peritoneum, with numerous very small tubercles upon the parietal and visceral membrane, and free serous fluid in the abdominal cavity. In all of these cases there was but slight disturbance of the general health. Some anorexia and heaviness and disinclination to move about were the chief symptoms. Some of the patients, too, had gray-colored stools, though not otherwise icteric.

The other three cases were of the dry adhesive form in which there was more general disturbance and often pain, and a considerable degree of matting together of the intestines and omentum.

The operation consisted only of an incision into the abdomen, and, after allowing the free fluid to escape, closing up of the wound. No washing or manipulation of the cavity was done in any case.

**Deutsche Med. Wochenschrift*, No. 29, 1893.

The four exudative cases all made a lasting recovery. In each, microscopic examination of the tissue showed characteristic tubercular structure, giant cells and in two cases the presence of bacilli. The three other cases all showed caseous tubercular nodules with bacilli. One case recovered from the operation and after four and a half months was still relieved from much of the pain and discomfort, though not at all well. The other two cases died with little or no relief.

After discussing these cases in detail he draws the following conclusions:

1. Peritoneal tuberculosis is spontaneously curable; the dry form in very few, the exudative form in a very large number of cases.

2. All forms may be cured or at least relieved by laparotomy, even when other treatment, including puncture, has failed.

3. The results of the operation depend upon (*a*) the form of the disease, the best results being obtained in the cases of effusion; (*b*) the duration of the illness; (*c*) eventual complications.

4. The operation is contra-indicated in advanced diseases or those with marked tuberculosis of other organs.

5. No explanation can be given of the reason or manner of the curative effect.

## NEWS AND MISCELLANY.

### George W. Childs.

No private citizen of this world has been more widely known or more highly appreciated among all classes and conditions of men than George W. Childs Philadelphia sat in sorrow nearest his bier, but all our great cities, the country at large and the world feel his loss. Everywhere the press and pulpit emulate each other in sorrowful, yet grateful tribute to his memory.

The public is familiar with the brief record of his exodus. January 18th, he suffered from an attack of vertigo, which was almost immediately followed by paralysis. The tenderest affection and the best medical skill watched over his prostrate form and did all that both could suggest for his recovery, and the intervention of Infinite love and power was invoked in churches of all faiths, Jewish and Christian, Catholic and Protestant. But the course of nature and the Supreme will disposed otherwise. He passed away in the early morning of February 3d, and his remains were laid to rest beside those of his friend, Anthony J. Drexel, who preceded him by just eight months.

A facile pen, that of the Rev. George Dana Boardman, briefly sketches his character and career thus:

"Exemplary in life, high in ideal, steadfast in pursuit, conscientious in method, successful in accomplishment, just in dealings, truthful in engagements, charitable in judgments, strong in convictions, courageous in expression, gentle in manner, chivalric in journalism, enthusiastic in friendship, public-spirited in citizenship, boundless in charities, cosmopolitan in range, contemporaneous in gifts, architectural in career—in brief, Christian in character,—himself is his own best monument; his tributes to the great and his gifts to the poor being his own memorial windows.

### The Anti-Dispensary Party win the Day in New York.

Monday night the 15th ult., the most exciting election ever held by the New York County Medical Association was witnessed.

There were three candidates in the field running for president; and singular to say, they were all objectionable, though in varying degrees.

Dr. McLeod's candidacy was distasteful because he had been president three successive years; and, it was righteously felt that it was time for him "to step down and out," and make room for some ambitious aspirant from the younger crop.

Dr. Tucker Harrison, another candidate, though, like Dr. McLeod, admired and respected by all the members, yet had been president in the near past, and it was thought best not to further encourage him to seek presidential honors.

Those two honored veterans were confronted by a young man quite unknown in New York, Dr. Ferdinand Valentine, who was a member of the association but two years, but he proved that he was not wanting in fighting metal, and gave his opponents all they could do to prevent themselves from total annihilation.

On the night of the election the Valentine faction, which came in great force, and moved compactly, had hustling about the city, in every direction, while the rain fell in torrents, several coaches and cabs, to bring in the lame, the aged and the invalid.

The McLeod columns well compared with the magnitude and solidity of the Valentine forces. Rumor was now scattered, that Valentine had been a homeopathic physician; that he was yet an "unrepentant sinner;" that he and his faction only wanted to make the association an annex to another polyclinic, which New York is threatened with; that they were the same gang of specialists that brought disaster, disunion and ruin into the ranks of New York physicians ten years ago.

This item of news, which, however, contained more truth than poetry, produced a smiting effect among those who had come to rush on the young candidate.

Now that they were not to be worsted, they resorted to new tactics, and charged Dr. McLeod's manager, the candidate for vice president—Dr. A. D. Ruggles—with treachery and treason. A motion to put him on the rack was pressed by Dr. W. R. Pryor; but the president prudently choked him off, on a rule of order, and the balloting went on.

It was nearly midnight when the polls closed. On the first ballot McLeod, closely pressed by Valentine, came out first. Harrison was only third, though the Southern vote was thrown almost for him.

Now, as no candidate had a majority, a second ballott was cast, when the Harrison men, almost in a body, went over to McLeod, when he secured a majority; though, to the last closely forced by Valentine.—*Times and Register.*

## ORIGINAL ARTICLES.

### A FEW CONSIDERATIONS ON THE SUBJECT OF CHOREA.

J. A. BAUGHMAN, M. S., M. D., Neoga, Ill.

We, who are prone to boast so much of the progress of modern medical science, were, no doubt, a little chagrined upon finding that he of the polished stone age, centuries before the building of the great pyramids, frequently and with success practiced trephining of the skull. In the light of this fact, no subject should be so time-worn or overburdened with literature, as to be of no interest to us in modern methods of medical investigation.

Our eagerness for prophylaxis, more rapid cures and better diagnosis, induces us to classify and generalize the great mass of written matter upon so common a subject as *chorea*. As Americans it may especially concern us to discuss a disease so sympathetic with our manners of living. The great tension under which our people are laboring industrially, politically and socially, is stamping them as the thin-blooded, restless, nervous American. One erudite penman has even accused us of creating a new disease—neurasthenia.

Closely associated to this is chorea, which is yet generally classed with the fast diminishing list of functional diseases. The symptoms of this disease scarcely need mentioning. It is the therapeutics, and more especially the etiology of the affection, that occupy the mind of the profession to-day, and upon these points there are yet wide differences of opinion. More than a score of causes of the disease are brought forward and defended by men in different parts of the world. Koch thinks it is not a neurosis, but due to a specific virus of an infectious nature. Last year a prominent Frenchman associated the staphylococcus aureus and albus with chorea in the relation of cause and effect. It, probably, was only a coincidence. Good men yet consider the cause as emboli in the cerebral arteries. Lyman, of our own society, classifies the affection under functional diseases of the brain, and states, no doubt truthfully, that it is purely a functional disease. I ascertained by writing to about thirty, that the physicians of our own state generally think of the disease as a neurosis, yet a few did not commit themselves on the subject. Though looking upon it as a neurosis, nearly all of them incidentally mention rheumatism as a possible cause.

Though the association of chorea and rheumatism was first recognized many years ago, an absolute relation of cause and effect has never been established. Lewis of Philadelphia, in a paper read before the Association of American Physicians, held in Washington last May, spoke of the interdependence of chorea and rheumatism, which was commented upon by Mitchell, Jacobi, Lyman and others. The assertion that the virus of chorea and rheumatism is identical will, no doubt, be influenced by the fact that curative remedies of the former disease often have no effect whatever upon the latter.

The literature of the last few years is very well agreed on some points connected with the disease, viz:

(1.) That females are more liable to the disease in the proportion of two to one.

(2.) The negro is not quite, but largely exempt from the disease.

(3.) Relapses occur in about forty-five per cent. of cases.

(4.) The disease shows a predilection for certain months of the year in the United States. This, however, is denied by Gowers, as the case in England.

(5.) No case is exempt; but from five years to puberty it is most common.

(6.) The mental faculties in most cases are considerably impaired.

(7.) The temperature of the body is unchanged.

(8.) It may affect only one side of the body, most frequently the left side.

(9.) There may be an hereditary predisposition to the disease, in which case it is incurable.

One of the points on which there is a difference of opinion is the electric excitability of the nerves. In two text-books, issued within the last year and-a-half, in this country, there are opposite statements upon this point. This, at first, may seem unimportant in studying the etiology of the disease, but when we remember the great similarity between electric and nerve forces—indeed, some believe them identical—the electric reaction of the nerves is by no means to be overlooked. That the organized body with its chemical changes is a great battery which creates and discharges nerve force is almost a self-evident proof.

In the electric paraphernalia of our offices, we must thoroughly understand the electro-motive force, intensity and constancy of our current, and the resistance which it encounters. These are facts we so seldom heed in the study of nervous diseases. In our materialistic age we rush madly on to the fray with those powerful weapons, scalpel, the test tube and microscope, forgetting that the very science we are creating is but the production of a higher science, that of the mental and vital operations, which are so intimately associated with tissue metamorphosis that without their relation we have no life. The mind and body have been evolved together, and should be a mutual fit.

The physical environments and mental facts cannot properly be studied apart from one another. To understand the nerve as a recipient of centrifugal impressions and as a conductor of force; and to understand the impression itself, is of the utmost importance in the study of such a disease as chorea. That the disease is often due to an intoxication of the centers of co-ordination seems probable from the many diverse signs we meet; yet the co-ordinate center need not necessarily be the affected area. Is it not possible that the conductivity of the axis cylinder is diminished or that the insulation has undergone a chemical change, which interferes with the transmission of the motor impulse? Chlorosis is so common in chorea as to suggest that the whole nervous system lacks some important element, probably oxygen.

The derangement is not necessarily in the brain, as a division of the cord is not followed by a cessation of bodily contortions. The fibres of the peripheral nerve trunks are liable to degenerations independent of lesions of the cerebro-spinal axis; and these changes may exist in chorea, thus interfering with force discharge and transmission; giving an uneven current, such as we have in a defective Faradic machine.

Thus the relations of the mental and motor energies are broken. They no longer go hand in hand; the motor units being irregularly discharged or transmitted in spite of the mental rheostat.

The molecular waves of force have no controlling influence, and, if they coincide, the intensity of their effect is increased; but if they stumble one over another, self-neutralization and inhibition take place, all objectively manifested in the abnormal rhythm of muscular action.

Chorea from fright is, perhaps, best explained in this manner, the great mental shock replacing for a time, or interfering with the rheostatic action of the mind. This irregular discharge need not depend on macro- or microscopical lesions. The changes, probably, are as wholly beyond detection as they are in neurasthenia. Just why some metals are better conductors of electricity than others is not fully known; no more do we know why one person is of a neurotic and another of a phlegmatic temperament, unless that subtle relation of mind and matter, that current controller of the human body is different in the two individuals in the chemical part of its constitution.

A disease dependent upon such a derangement would certainly be deemed a functional one.

A case of chorea with one peculiar feature came under my observation within the year. It was a strong, unmarried lady of twenty years. The exciting cause seemed to be grief. The muscular spasms came at regular intervals, about four per minute, and affected nearly all of the voluntary muscles of the body. As regular as clock-work, a violent muscular spasm, of only an instant's duration, shot through the body. The reflexes were normal and the patient felt perfectly well otherwise. There was an hereditary taint, a cousin or two having suffered from incurable chorea. To me the peculiar feature was, that by firm pressure on the first dorsal nerve of the right side, where the nerve passes over the spine of the scapula, the spasm could for a time be wholly surpressed, and at all times be greatly ameliorated. I discovered this only by accident. No anatomical changes could be seen at this point. Under heavy doses of antipyrin, recovery took place in about one week. Will some one explain why pressure on the point indicated above arrested the spasms, or whether I was mistaken in my diagnosis?

Sinkler gives a very interesting paper in the *Medical Record*, on hereditary or Huntington's chorea, in which he reports and re-reports a number of cases, carefully showing the hereditary tendency of the disease. He admits the pathology to be still unknown, but thinks it probably due to developmental defects. He calls attention to the fact that mental deterioration occurs in most cases, many of them landing in the insane asylum. He concludes that there are two varieties of this form of the disease, the division depending upon the time of mental degradation.

Many other papers, meritorious and common place, have been written during the year on chorea, offering nothing especially new on the subject.

Although chorea tends toward a spontaneous recovery, many cases are troublesome and even incurable, hence demand the best skill and care of every conscientious practitioner. The treatment of the disease in the last three or four years has undergone a considerable variation. Starr says the neurotic element, perhaps, is the one requiring attention. All peripheral irritations, such as intestinal worms, undue excitement, etc., must be removed.

The condition of the blood is one of the prime factors in the treatment of chorea, hence the universal use of iron and arsenic. While these are, perhaps, our most valuable remedies, arsenic is not an ideal one. But a short time ago, *The Lancet* reported a frightful case of pigmentation of the skin and paralysis, from the administration of the drug in chorea.

However wonderful the results of this remedy alone, we will hardly assume its power to remove cerebral emboli, neutralizing the rheumatic virus or changing the specific gravity of the optic thalamus, all accidental conditions that have been thought causative in chorea.

Antipyrin is rapidly coming to the front as a very valuable drug in chorea. The French are using it extensively and give very gratifying reports as to its efficacy.

Personally, in a few cases I have found it very efficient, even with its doubtful action upon the red blood corpuscles.

It is used in doses of from fifteen to sixty grains per day, associated with the same amount of sodium bicarbonate.

It often gives very rapid results. See recommends a combination of antipyrin and arsenic.

Electricity is recommended by a few, but the great majority of clinicians find it of little or no value. In rheumatic subjects the salicylates, or oil of wintergreen, should always be combined with the other remedies. It is very interesting to note that hypnotism or commanding the patient to remain quiet has been successful in treating chorea, within the past year. What a wide range for speculation this fact gives to the deductive mind. Is it not an excellent illustration of the possibility that the choreic movements are a direct outcome of those delicate, subtle changes, of which we know so little, under the direct control of the will?

Luys claims to cure these by means of revolving mirrors, which exert an influence only through the channels of the mind. He also claims that these cases are the most common ones we meet. It is not generally known—at least not practiced—that prolonged sleep in cases of chorea gives the happiest of results. Joffray recommends for the induction of sleep in these cases, chloral hydrate.

## THE DANGERS OF INFECTION BY PERSONAL CONTACT WITH DISEASES NOT REGARDED AS ACTIVELY CONTAGIOUS OR INFECTIOUS.

J. W. IRWIN, M. D., Louisville, Ky.

[ABSTRACT.]

As no pretense will be made for any claim to priority for the subject of the remarks I have to make, I shall offer no apology for bringing to your notice a few of the facts on "the dangers of infection by personal contact with diseases not regarded as actively contagious or infectious." Nevertheless, I cannot hope to escape criticism at first sight by those who may believe that the discussion of this subject is untimely, in that special reference will be made to the double occupancy of beds which has been the rule observed by our ancestors from time immemorial, and it may be thought good enough for us now.

I am not unprepared to hear any reasonable amount of criticism, and I shall take refuge against it in the light of an advanced state of observation, which has given us more accurate knowledge and has replaced sophism by logical conclusions which physiological facts have shown to be more in accord with the laws of self preservation.

For many years there have been certain diseases recognized as not contagious or infectious, and yet persons who were known to be in good health before coming in contact with those afflicted by them, often became their victims. The *materies morbi*, which were at work causing many diseases, were accounted for hypothetically only, until Koch announced his discovery of the germ of consumption. Then it was that important light was thrown upon the spread of diseases which had hitherto been shrouded in mystery. Since Koch's important discovery of the tubercle bacillus, the science of mycology has received new impetus, and it is making rapid progress in the search for truths.

The danger of certain insidious diseases being transmitted by contagion or infection, before Koch's discovery was too little regarded by physicians. Now the importance of prevention is being fully appreciated, and it is receiving careful consideration at the hands of physicians and others whose duty it is to protect the health of those whose lives are entrusted to them.

Another important and more recent discovery has been found in the fact that there are certain disease germs which do not live in the normal air, and others that do live and thrive in it. Whether or not this peculiarity applies to any of the germs found in the diseases of the air passages, I have seen no mention made of it.

Now, let us consider the character of the excretions and exhalations which are present in every person in a state of health, and we find certain poisonous ingredients which render their immediate atmosphere impure. When these poisonous products are inhaled, they tend to weaken vitality and render the recipient more susceptible to the action of disease germs, while had these products been first subjected to the free air, their properties would have been changed and made inert.

In those suffering from disease, more poisonous products are present in their immediate surroundings, and in addition there are disease germs awaiting a suitable soil in which to grow and multiply.

There are many diseases of the air passages, indeed nearly all of those affecting the mucous membranes, that are now recognized as contagious or infectious, as well as the more insidious disorders which affect the lungs. Contact with these diseases render the subjects more liable to be infected by them. Children sleeping together in the same bed often convey the seeds of disease to each other through the respired air, which a distance of a few feet from each other might have prevented.

Imagine, by way of illustration, two persons occupying the same bed, one of which is sick and the other is well; the well one is inhaling the breath as it leaves the nostrils of the sick, warm and laden

with its millions of disease germs, and it will be readily understood how even insidious diseases not actively contagious or infectious may be transmitted to others. There are few physicians who have not been brought face to face with the sad scene of a house deprived of its most useful member for the want of precaution against those insidious germs which were conveyed from the lips or in the respired air from the lungs of a bedfellow who was the victim of consumption. It is, therefore, no longer any surprise to find that the husband or wife has become the subject of consumption after sleeping in the bed together, one of which being a victim to that insidious malady which knows no foe.

The remedy of this evil suggests itself, and it has already received some recognition abroad. Do away with the use of double beds, and replace them by single ones furnished with separate clothing. The same room may be occupied by the husband and wife, and the beds may be placed near enough to each other for companionship. This arrangement of the beds will cause the poisonous products of the exhalation of persons to become diluted and changed by the air, and rendered less injurious to health when again inhaled. The advantages to be derived from the use of single beds will become apparent for reasons other than for the prevention of the disease. The arrangement will, in most cases, tend to preserve the sense of delicacy which closer contact sometimes dulls. Again, when persons are fatigued from overwork or mental worry which give rise to insomnia, and cause them to become restless and roll about, or, when necessity compels them to leave the bed, the companion will not be awakened or otherwise disturbed. There are many other disagreeable features which annoy sensitive and wakeful persons, who occupy together double beds, such as heavy breathing, snoring, and other strange respiratory sounds, which distance would render much more endurable. Late or irregular hours on the part of a companion for retiring, often awaken the sleeper and his sleep is over for that night.

Many other illustrations might be given to show the injurious effect of persons sleeping together in double beds.

We live in an age of reason and observation, and as guardians of the public health, true to our trusts, it is our duty to consider matters of such vital importance as I have referred to in this short essay.

## PROCIDENTIA UTERI.*

CHARLES P. NOBLE, M. D., PHILADELPHIA.

The condition of procidentia uteri is of importance to the practitioner because of the frequency with which it exists, and because of its curability when properly treated. Without proper treatment it becomes progressively worse, until finally, in some cases, such changes ensue in the posterior vaginal wall and pelvic floor that its curability is questionable. In order to appreciate the treatment of procidentia it is necessary to refer to the factors engaged in maintaining the pelvic organs in their normal relations, and also to the causes which tend to produce their downward displacement, and especially to the displacement of the uterus. The tendency is strong to consider the uterus separate and apart from the other pelvic organs, especially in relation to the causes of its displacement. This tendency is unphilosophical and results in confusion and in erroneous inferences. In general, the same factors preserve all of the pelvic organs in their normal relations, and the same factors are at work in the displacement of each and all of these viscera. The influence of atmospheric pressure in maintaining the pelvic viscera in their normal relations is frequently overlooked. The peritoneal cavity is a shut sac immediately in relation with the thoracic cavity, being separated therefrom by the diaphragm. As under normal conditions the urethra, vagina and rectum are closed canals, impervious to air, it follows that atmospheric pressure has a very positive effect in maintaining the pelvic viscera at a certain level. This level is fairly constant, as the capacity of the thorax (which has a free communication with the exter-

* Read before the Obstetrical Society of Philadelphia, January 4, 1894.

nal air) is fairly constant. This influence of atmospheric pressure has been treated of by writers, especially by Thomas, under the heading of "The Retentive Power of the Abdomen." Atmospheric pressure is the constant factor giving the abdomen retentive power. Variations in the tonicity of the abdominal muscles interfere with this function; and when the abdominal walls become very lax from over-distention, or from atrophic changes, this factor in maintaining the normal status of the pelvic viscera becomes largely inoperative.

Habits of dress also modify the influence of the intra-abdominal pressure in maintaining the pelvic viscera in position. The use of tight corsets, by restricting the excursions of the diaphragm, tends to prevent the ascent of the pelvic viscera which takes place normally with each expiration. Also, by displacing the abdominal viscera downward and forcing the bowels down upon the pelvic organs, tight lacing acts by driving downward the pelvic contents. Tight lacing kept up for a long period of time, acts further by inducing an atonic condition of the muscles of the trunk, thereby interfering with the normal intra-abdominal pressure, and with the so-called retentive power of the abdomen.

Another factor which is not much dwelt upon is the adipose tissue which is present in the pelvis. When a woman becomes rather suddenlie and markedly emaciated, the loss of adipose tissue in the pelvis favors the displacement of the pelvic viscera. During and after the time of the menopause, when the fatty tissues about the genitalia very generally undergo absorption, displacement of the pelvic viscera often occurs. Prior to this time, in many cases, although various injuries which favor displacement may have been sustained, yet, owing to the presence of the fatty tissue, displacement does not result. In these cases, after the atrophy of the fatty tissues occurs, prolapse of the pelvic viscera takes place.

Other factors, not directly connected with the pelvic structures themselves, which must be considered are certain habits of patients. Too laborious work favors displacement of the pelvic organs, especially when their proper supports are for any reason weakened. As a rule, those who are called upon to do laborious work have vigorous muscular systems, and with intact pelvic organs no harmful consequences ensue. Such consequences are most apt to ensue when a feeble woman is called upon to do extremely heavy work, or when such work is performed by one who has suffered injury to the pelvic supports.

Constipation favors prolapse of the pelvic viscera for very much the same reason as does too laborious work—the straining at stool accomplishing the same result as the too laborious work. Constipation acts also by favoring pelvic congestion, which, no matter how induced, always favors displacement of the viscera by inducing laxity of the tissues.

These general considerations are of importance, not only as permitting the proper appreciation of the causes which underly displacement of the pelvic viscera, but also for the very great assistance in the curative treatment of these disorders which a proper appreciation of the above facts afford.

More important, however, than the forgoing are the proper supports of the pelvic organs themselves. In women, as in men, the entire pelvic contents are supported by the action of the levator ani muscles, the pelvic fasciæ, the sacro-sciatic ligaments and the pelvic connective tissues. It is true that the peritoneum and the connective tissue which lies under it affords some additional support from above. The bladder, the womb and its appendages, the vagina and the rectum, and the super-imposed, small intestines are all supported by the structures referred to. They make up the pelvic floor, and upon their integrity the normal position of the pelvic viscera depends. The connecting tissue of the peritoneum about the bladder and also about the rectum and the other organs has a minor influence in fixing within certain limits these organs. The uterus, more especially, receives other support than that of the pelvic floor—the utero-sacral, the broad and the round ligaments affording a certain amount of support to this organ. The careful study of the whole subject, however, is convincing that these ligaments, and the retentive power of the abdomen, brought about by the atmospheric pressure, are of importance, rather as maintaining the uterus in its normal position of anteflexion than in keeping it at a certain plane in the pelvis. Undoubtedly, these factors have a certain influence in preventing downward displacement of the uterus, but all combined

they are not of so much importance as is the normal pelvic floor.

The principal support which maintains the pelvic viscera in their normal relations is the pelvic floor, the most important structures in which are the levator ani muscles and the pelvic fasciæ. Upon the integrity of these structures the support of the pelvic viscera depends. When these structures no longer perform their normal functions, either because of atrophy or because of laceration of their tissues, downward displacement of the pelvic viscera is favored. This point cannot be too strongly insisted upon; nor can it be made too clear that these are the structures of importance in giving support to the rectum, vagina, bladder and uterus, rather than an imaginary structure formerly known as the perineal body.

The old theory that the perineal body was the prime factor in pelvic support must be definitely abandoned, because it is based in error. There is no such structure as the perineal body. The tissues between the lower end of the vagina and the rectum are certain slips of the levator ani muscles, the transversus perinei muscles, the deep and superficial fasciæ, connective tissue, blood-vessels and nerves, and the bulbo-cavernosus muscle. The ends of these slips of muscle unite in the median line, forming a somewhat tendinous union. The amount of tissue between the rectum and vagina is very much overestimated. Any one can demonstrate that this septum is scarcely more than a third of an inch in thickness if he will examine a nulliparous woman, placing the thumb in the vagina and the forefinger in the rectum. Such an examination will dispel from his mind any idea which he may have had that there is a large wedge-shaped mass of tissue situated between these two canals, which, in virtue of its size and shape, holds up the pelvic organs.

Women having the greatest amount of tissue between the anus and posterior commissure of the vulva, have really the least support for their pelvic organs. This fact, so directly at variance with the ancient teaching upon this subject, is easily explained. When the levator ani muscle, or a part of it, has been torn through, the pelvic floor drops down, and if the skin over the perineum has not been ruptured it stretches out. The anus drops down toward the feet and back toward the coccyx, so that the skin between the anus and the vulva is put upon the stretch. These facts are easily capable of demonstration, and any one who doubts them can easily satisfy himself of their correctness. They show also that visual inspection of the perineal region is insufficient to test its integrity. Cases which have appeared to receive no injury, may have severe lacerations within the vulva; and other cases which appear to have been badly torn because of the involvement of the skin over the perineum, may, in reality, have escaped without injury to the deeper and important structures of the pelvic floor. The examination, to be complete, must include palpation of the levator muscles to test their powers of resistance when drawn upon by the palpating fingers.

The physiology of the support of the pelvic viscera appears to be as follows: The rectum and vagina receive direct support from the levator muscles. Their orifices are kept closed partly by the action of these muscles, and partly by the sphincter ani and bulbo cavernosis muscles. The anterior wall of the vagina and the bladder are supported upon the posterior wall of the vagina; and the uterus and its appendages are supported upon these structures. The connective tissue attachments of the organs named, of course, are of service in limiting their mobility; and, in addition, the proper supports of the uterus are of much importance.

When all of the factors concerned in maintaining the pelvic organs in their proper relations are normal, these organs are retained in their proper positions. Their downward displacement is due either to increased pressure from above, or to diminished support from below, or to both. The influence of heavy lifting, of tight lacing, and of constipation, and of emaciation, in favoring displacement, have been considered. Two other causes remain, one is retro-displacement of the uterus, and the other is increase in the size and weight of the uterus. The influence of the second cause in favoring downward displacement is so clear that it is unnecessary to enlarge upon it. The influence of retro-displacement in favoring descent of the uterus is equally clear, if the anatomical and physical relations of the pelvic viscera are remembered. The uterus, in its normal position of ante-flexion, lies with its axis at an acute angle with the

vagina; indeed, when the bladder is empty, the fundus of the uterus approaches very close to the anterior wall of the vagina. In this position, when the uterus is forced downward, it simply tends to push the anterior wall of the vagina against the posterior wall, when it meets with the resistance of the pelvic floor; hence the vagina is not distended. In this position the force of the intra-abdominal pressure falls upon the posterior wall of the uterus, and maintains the uterus in its normal anti-flexed position. If, for any reason, the uterus becomes retro-displaced, its axis becomes parallel, or almost parallel, with the axis of the vagina. Intra-abdominal pressure falls upon the fundus and anterior wall of the uterus and the vesico-uterine pouch, and tends not to drive the cervix and the anterior vaginal wall against the posterior vaginal wall, but to drive the whole uterus downward along the axis of the vagina; thus to a greater or less degree, inverting the vagina in its descent. In this malposition of the uterus, intra-abdominal pressure, instead of being a conservative force tending to maintain the uterus at a certain level, becomes a factor of evil tending to produce procidentia uteri and prolapse of the bladder. The degree to which these displacements are carried depends, of course, upon the amount of intra-abdominal pressure, upon the laxity of the tissues in an individual case, and upon the amount of resistance met with from the pelvic floor. So much for the causes acting from above.

When the pelvic floor becomes weakened, either by laceration or atrophy of its structures, adequate support to the pelvic viscera is no longer afforded. The pelvic floor drops downward and backward, the introitus vaginæ gapes open, the posterior wall of the vagina drops away from the anterior wall, the rectum tends to bulge forward through the gaping vulva, constituting a rectocele; the anterior wall of the vagina and the bladder tend to prolapse into the introitus, constituting a cystocele; and in turn the uterus tends to come down (partly from lack of support, and partly through the influence of pressure from above), constituting a prolapsus or procidentia uteri.

The proper study of every case of procidentia involves a careful investigation into each of these factors which may be concerned in its production, and upon the proper recognition of exactly what underlies each case, depends the scientific and curable treatment of the disorder.

In my experience, by far the most important cause of procidentia, is laceration of the pelvic floor, especially lacerations involving the levator ani muscle and pelvic fascia. This injury is the primary cause of procidentia in ninety-nine per cent. of the cases which come under my observation. I see numerous cases of slight prolapsus or descensus uteri, where the uterus simply descends one inch, or an inch and a half, which are due to other causes than a torn pelvic floor. Such causes as tight lacing, hard work, constipation, pelvic congestion, etc., can bring this about. But in my experience these causes, broadly speaking, are incapable of producing complete procidentia of the uterus. There are exceptions to this rule, but only one has come under my observation. This was a case of complete procidentia in a nulliparious woman having lax tissues, who had been compelled to do laborious work with heavy lifting. Her uterus doubtless had become retroverted, then prolapsed, and, finally, had been forced down so low that it protruded between the labia. This woman had a lax, but intact pelvic floor. She was cured by changing her occupation, the use of tampons for a time, followed by a Smith-Hodge pessary.

*Treatment.*—As the primary cause of procidentia is a torn pelvic floor, it follows that if lacerations of the pelvic floor were properly repaired at the time of their occurrence, or shortly thereafter, that procidentia uteri would be prevented. In other words, the way to prevent procidentia uteri is to do immediate perineorrhaphy in all cases of laceration of the pelvic floor following labor. It is unnecessary at this time to go into the details concerning the technique of immediate perineorrhaphy. I shall simply say, that in this operation the sutures should be placed just as carefully, and in the same manner as for the secondary operation. The patient should be anæsthetized, the parts well exposed, and the suturing begun at the upper angle of the tear, no matter how high up this may be. The sutures should be tied as they are introduced, so that when the last suture is introduced and tied, the operation is completed. Immediate perineorrhaphy can be done at any time within

twenty-four hours after labor, and doubtless even later, with complete success. If, however, the suturing is postponed more than six hours after the injury has occurred, it is better to freshen the raw surfaces by scraping them with a knife. These lacerations will be found, almost invariably, to extend up one or both sulci of the vagina. They are never median, unless the tear extends through the sphincter ani, and then splits the recto-vaginal septum. It is far better to postpone immediate perineorrhaphy for six, ten, or twenty-four hours, and to have proper assistance, than it is to attempt the operation at the close of labor, when the physician is tired out, the patient exhausted, and, perhaps, without anæsthesia, because no one is present to administer the anæsthetic. The practice somewhat in vogue of putting in one, two, or three sutures from the skin perineum cannot be too strongly condemned; because all severe lacerations extend one, two or three inches up one or both sulci of the vagina, and cannot be reached by sutures introduced from the skin perineum. All that such suturing can accomplish is to unite the unimportant superficial structures of the skin perineum, while the torn levator muscles are not included in the sutures.

The other factors which produce procidentia are those which increase intra-abdominal pressure (such as tight lacing and laborious work), retro-displacement of the uterus (which favors procidentia, because in this position intra-abdominal pressure tends to drive the uterus along the vagina, and parallel with its axis), pelvic congestion, brought about especially by constipation, sub-involution of the uterus and other pelvic organs, and in rare cases, the presence of a tumor adds to the weight of the uterus. A perfect prophylaxis of procidentia uteri involves the prevention or cure of all of these conditions.

When procidentia really exists certain conditions are always present. The uterus prolapses into or through the vulva, and its proper ligaments are overstretched. The anterior vaginal wall and bladder are prolapsed, and in many cases a large cystocele is present. The posterior vaginal wall and rectum have dropped downward and backward with the pelvic floor; and the rectum may, or may not, have bulged through the open introitus, if so, constituting a rectocele. In many cases the uterus will be found elongated, constituting the condition known as supra-vaginal elongation of the cervix. This is brought about by stretching of the cervical tissue, rather than by its hypertrophy. In such cases the fundus uteri occupies a higher plain in the pelvis, than would appear from the position of the cervix. In many such cases the uterus measures four, five or even more inches; and yet often reducing the procidentia and putting the woman in the knee-chest posture, it will be found to measure only three or four inches.

The method of operating which I have followed in treating this class of cases is to do a high amputation of the cervix, anterior colporrhaphy, and Emmet's perineorrhaphy. The amputation of the cervix reduces the size and length of the uterus, and through the way it is done draws the vagina to a higher point in the pelvis. The anterior colphorrhaphy takes up the slack under the bladder and makes the anterior vaginal wall a straight line from the pubic arch to the cervix, as it should be. The perineorrhaphy restores the pelvic floor to its normal condition, and gives permanent support to the bladder and uterus. Naturally the uterus should be maintained in ante-flexion, and if after an operation it does not assume this position, a Smith-Hodge pessary is introduced to maintain the uterus in its normal position. Practically, I have seldom found this necessary even for a short time, and of the very many operations which I have done for procidentia, so far as I know, not a single woman is now wearing a pessary.

In amputating the cervix, the woman is placed in the lithotomy posture; the field of operation made asceptic; the cervix is seized with bullet forceps and drawn down; the vagina is cut loose from the cervix; the bladder is stripped off in front, and the sub-peritoneal tissues stripped off behind. The lateral attachments of the cervix (the bases of the broad ligaments) are now ligated and cut away. About an inch of the cervix is now amputated; then the cut edges of the vagina are stitched to the stump of the cervix, the mucous membrane of the vagina to the mucous membrane of the cervical canal; thus covering in the stump, and securing primary union. This operation draws up the vagina to the cervix at its new level. Also, it very materially reduces the size

and weight of the uterus, not only through removing part of the structure, but by the process of involution which it induces.

Anterior colporrhaphy is next performed. In those cases in which the bladder has not been markedly prolapsed a simple oval denudation is made, which is closed with a continuous catgut suture in two layers. In marked cases of cystocele Stoltz's operation is done. This consists of a circular denudation, with a single running suture placed like the drawing-string of a bag, and tied in the same way. The operation is quickly done, and secures a firm point of cicatricial union under the bladder. I believe that the merit of the operation consists not only in the ease and rapidity with which it is done, but also that it offers a more permanent resistance to the descent of the bladder at a future time.

Emmett's perineorrhaphy is then done, and is that part of the operation which makes the cure a permanent one. The operations upon the cervix and upon the bladder would for a time overcome the prolapse of these structures, but when the woman got about on her feet again, the prolapse would simply reappear were not the primary cause of the trouble (namely, the lacerated pelvic floor) repaired. In restoring the pelvic floor I have not been content with doing the regular Emmett's perineorrhaphy, but taking this operation as a basis, I have made the denudation as extensive as possible; in this way not only bringing together the sundered structures, but, in addition, making the vagina as narrow as possible, and also sewing up the vulva to a certain extent. In this way the vagina can be reduced in size, so that it scarcely admits more than the index finger—an end to be desired in every bad case of procidentia.

In doing amputation of the cervix, a few heavy silk ligatures are used, but most of the operation is done with catgut. It is well to have a silk ligature to pass through each lip of the cervix into the cervical canal, so as to have two silk ligatures at the point where the future os uteri is to be, as otherwise the raw edges of the cut vagina might unite, which would necessitate making an external os at a later day. The basis of the broad ligaments can be tied off with catgut, and almost all of the sutures about the cervix can be of this material. This is a decided advantage, as it is not desirable to make traction upon the perineum to remove these sutures for some weeks after the operation. In doing the colporrhaphy, when the oval denudation is made, the wound is closed usually with a running catgut suture placed in two tiers. Usually one or more silk sutures are introduced to act as stays. In operating upon the pelvic floor, the upper sutures are of catgut and the lower ones of silk. This obviates the necessity of removing the upper sutures, which embrace only the cut vaginal walls, and which are used only to help in narrowing the vagina. Silk is used in suturing the torn ends of the muscles and for the external sutures. The ones in the skin are removed in a week, those in the vagina after two weeks.

It is wise to treat patients having procidentia for some weeks prior to their operation. The uterus should be reposited and kept in its position by means of tampons. In order to secure this object it is at times necessary to put the woman to bed. In very bad and long-standing cases of procidentia, the mucous membrane of the vagina loses its proper character, and becomes very much like skin. It is of decided advantage to reduce the procidentia and to treat the condition with glycerine tampons, which helps to restore the parts to a more nearly normal condition. After the operation it is best to keep the patient in bed for at least two weeks, and preferably for three weeks, and then to permit only a very gradual resumption of her ordinary occupation. Such patients should be cautioned against straining or lifting, and should be informed that it requires weeks for a wound to become thoroughly consolidated.

It is, perhaps, wise, in this connection, to say a few words about the use of the pessary for procidentia. Excepting those rare cases in which the procidentia has occurred in spite of the fact that the pelvic floor is intact, the use of the pessary for this condition is clearly illogical. A pessary can never restore a torn pelvic floor; and if this accident has been the cause of the procidentia, any treatment except the repairing of the injury is clearly illogical, and can be only of temporary value. The pessary is a useful instrument in the treatment of slight descensus and of retroflexion of the the uterus when the pelvic floor is intact. The pessary should

be supported from below, partly by the vagina itself and largely by the encircling slips of the levator muscle. It should never get its support from the pelvic bones, which is what happens when a large pessary is introduced to hold up a procidentia when the pelvic floor is widely torn. Used under these circumstances, a pessary must be large in order to be retained, and when it is large it invariably presses against the pubic bones. It is not necessary to point out how illogical this use of the pessary is in order that its application may be condemned.

## VACCINE VIRUS.*

H. M. ALEXANDER, M. D.

Nearly a century has elapsed since Dr. Edward Jenner, the discoverer of Vaccine Virus, inoculated his first patient, and proved to the world the efficacy of his theory of vaccination, as the preventative of that dreaded disease, small-pox. As has always been the fate of every new theory, invention, or innovation in its infancy, Vaccine Virus met, for a time, with violent opposition, yet the learned Jenner lived to be feted in the streets of London, his path being strewn with flowers, and was finally tendered a testimonial of ten thousand pounds, by an Act of Parliament, in recognition of the great boon he gave to mankind. But important discoveries are slow to adoption, and owing to bigotry and superstition, are seldom appreciated fully in the age of the discoverer. The evolution of Vaccine Virus was, then, necessarily slow. Great difficulty was experienced in procuring Vaccine from the animal, and the use of the crust, taken from one person and applied to another, which is known as Humanized Virus, or vaccine, was adopted. This method was continued for many years, when it was discovered that a great number of diseases, especially skin diseases, and the most vulgar ones to which the human system is heir, were being conveyed from arm to arm.

### DESIGNATED HUMANIZED VIRUS.

We shall pass over the history of the period which elapsed from the beginning of the Nineteenth Century until the propagation was begun in America in 1870, for the history of this period, as we glean it from the writings of many authors, is very conflicting. Its efficacy as a protective agent was thoroughly proven in many instances, while there were others that left some doubts as to its ability to protect against the dread disease, small-pox. Our own experience has forced us to believe that these great deficiencies in protective power were largely due to the fact that Humanized Virus was much used, which in these cases of failure had greatly degenerated.

### SOURCES OF AMERICAN PROPAGATION.

Whether true cow-pox was found among the cattle frequently prior to 1866 is not certain, but in that year a case was found in Beaugency, France, and it was from this strain that Bovine Virus was imported into America, and its propagation from heifer to heifer introduced into the United Stated in 1870 by the late Dr. Henry A. Martin. In the decade which followed, the propagation of Vaccine Virus was begun in various sections of the country. The methods employed, however, were of the crudest nature, and much of the propagation of a dangerous character. In many instances, propagation is still carried on in unclean stables, located in filthy city alleys, where the virus produced is of necessity subjected to dangerous contamination of the surrounding filth; the cattle are usually procured from city stock yards —generally heifers—but very frequently decrepit, old cows, that have shown some organic weakness. Only an external examination of them can be made, and naturally disease-bearing tuberculosis is not always avoided. As a result, the greater portion of the Virus procured in this way, instead of affording protection against small-pox, merely produces ulcers of a dangerous and most painful nature.

### LOCATION OF VACCINE ESTABLISHMENTS.

It is important that an establishment for the propagation of Bovine Virus should

*Address before the Fourth Pharmaceutical Meeting of the College of Pharmacy, Philadelphia, Pa., January 16, 1894.

be located in the open country, where the advantages of pure air and perfect cleanliness can be found, and where every possible sanitary condition can be had. The buildings should be erected especially for, and devoted exclusively to, the propagation of Vaccine Virus. They should be models of perfection and completeness, while the water supply should be well filtered, and absolutely under the control of the propagator. Ample room should be given, that no crowding of cattle be called for. The operating should not be done in the stable, but should be in a spacious room, well ventilated, free from filth of every description, and perfectly dry, for dampness is an avowed enemy to Vaccine Virus. The stables wherein the cattle are housed should be clean, pure, and entirely free from foul or impure air.

### THE PROPER SELECTION AND PREPARATION OF THE CATTLE.

Instead of buying cheap, diseased, or decrepit cattle from city stock yards, the better plan is to rent heifers from one to two years of age, being reared by the farmers of the surrounding country for their future milkers. This enables us to use generations of the same stock, and therefore know all about them, giving the advantages of learning of the existence of any hereditary diseases that might naturally be overlooked in the most careful examination of the animal itself. When the heifers are brought to the farm, the first thing is to give them a close examination, then place them in the stables, groom carefully, and feed on bran mashes, until it is determined they are ready to become subjects. They should then be led to the operating room, and fastened. The method of this fastening differs greatly, but the one which I show you on the photographs distributed, has proven in my own hands by far the most satisfactory. By a simple mechanical arrangement the animals are easily turned over, resting on the strong portions of the ribs, near the vertebral column. They rest easily on these upholstered tables, and do not struggle, while all is done in a manner which preserves them from excitement. The inner portion of the flanks, back and above the udder, are then well shaven and inoculated with Vaccine taken from a former subject. This portion of the body is selected as it is the easiest to kept clean, and does not chafe. In some establishments the udder is selected, but experiments have conclusively proven that the udder is too warm a location, and usually results in confluence and malignancy. The abdomen, which is also sometimes selected, offers the same objection, as the animal cannot lie down to rest without lying on some of the vesicles, and developing excessive heat. After the inoculation, the heifers are taken to specially prepared stalls, where they are cared for and watched closely for an average of seven days and nights. When the vesicles are fully developed, the animals are returned to the operating room, the crusts are then removed with the handle of a scalpel, and the vesicles are thoroughly cleansed by sponging, and all foreign and impure matter removed.

### PREPARING THE POINTS.

The ivory points which are to receive the lymph which is now exuding from the vesicles, should be sterilized. They should then be placed in clamps of fifty each, so that the operator is not obliged to touch the points with his fingers. The points are coated by applying with a camel's-hair brush with which the operator absorbes the virus as it exudes from the vesicles. The points are coated twice, with the virus of two animals. The vesicles should not be irritated by the repeated application of the point to the surface, as is the case in most establishments, and which causes them to exude much serum, while the repeated handling of each point causes great danger in the way of septic poisoning. Besides this, when fifty points in one of these clamps are coated with one and the same brushful of Virus from one animal, and re-coated with another brushful from another animal, they will all be alike, which is not the case if the vesicle is irritated by a repeated application of hundreds of points to the tender surface. They should be carefully inspected, packed in glass, and bear the label of the propagator. Unscrupulous propagators, do not, as a rule, label their goods, but conceal their identity, which should always be a good reason for discarding them.

### SELLING THE POINTS.

Rate cutting and the great clamor of the cheap druggist, or the demand of sharp competition, have caused ivory points coated with mucilage to be placed upon the market at a very low figure, thus

driving the real article out for a time. These knaves, then finding that the total failure of their goods gave them much trouble, and that the druggist returned to the legitmate ones, added croton oil to their mucilage which causes a vesicle to form. The patient tells the physician that his arm is sore, and he, accepting the statement, believes the vaccine to have been all right, while the fact that it acts so quickly proves its worthlessness.

CAUSE OF FAILURES.

This brings us to the cause of failures being reported, not only where there has been actual failures, but where the physicians failed to wait long enough before making their reports. Not only do failures certainly result from the use of impure materials, but they also occasionally result from those of good source. Some few cases are insusceptible, but not many. Secondary vaccinations fail because they have been previously vaccinated, and are still protected. Other failures, even in primary vaccinations, are sometimes due to the fact that Virus was shipped in an over-heated car, and hence spoiled in transit. A still more frequent cause is that the Virus is exposed to excessive heat or moisture in the office or store of the druggist, or by the physician carrying it in his vest pocket. It can be guaranteed for sixty or ninety days, for Vaccine is not injured by age as frequently as is generally supposed, if kept in cool, dry apartments. In fact, we send it to China, Hindoostan and Palestine with success. Many physicians fail in consequence of their method of operating. We do not want to say that our method of vaccinating is the best, but we will give what we have found to be the most successful manner of proceeding, and also why we think others have failed.

HOW TO VACCINATE.

Our plan is to scarify the part thoroughly by scraping off the scarf-skin, and scratching the surface thus abraided in two directions, roughing it, so as to get the lymph retained close to the mouths of the absorbent vessels. The portion scraped should not be too large, as too large a surface often results in great violence, or an ulcer is produced where a simple vaccination was intended. We touch one side of the ivory point in a drop of water, shaking all possible off agian, then apply it by rubbing it well upon the scarified surface, depending largely for our moisture upon the amount of serum which exuded from the scarification to dampen it, and aid us in removing the Virus from the ivory point. Often this serum, with the water we have used, is excessive, when we can readily form a paste by the use of the other side of the ivory point which was not dampened in this manner. We are certain of getting a sufficient number of Vaccine corpuscles within reach of the mouths of the absorbent vessels, and to finish the operation we gently prick or scratch the arm with the point we have just used. Many physicians use too much water, and are unable to form a paste, the little corpuscles floating off, and being very glutinous, adhere to the skin; the physician thinks he has gathered them up, and finishes by getting all he can upon the scarified surface, but does not succeed in getting much else than the serum; the absorbent vessels exhaust themselves absorbing this material, and fail to get in any of the corpuscles required. Again, we have known of paste, when not finished by pricking it in, to have dried as a varnish beyond the reach of the absorbents, which had been closed by the rubbing process.

Another cause of failure is that hosts of physicians clamor for colorless points, forcing the propagator to give them as little as possible, in order to keep away from color, and then they use one point to two patients, when it was only intended for one.

VIOLENT RESULTS.

Violent results occur from the use of lymph containing filth, the use of irritating drugs, and the use of Virus that has been removed from the animal at the wrong time, for it should be taken early. They also occur from the use of cattle that are too old, which yield a great deal more Virus, but which is unnecessarily strong and irritating. Again, the violence may result from the neglect of the physicians to cleanse the arm prior to vaccination, or the use of an unclean lancet; that is, the one used continuously without being disinfected. The best way to disinfect a lancet is to dip it in alcohol after each application, and then touch it to a flame; but a more frequent cause of violent arms comes from the practice of dressing the arm after the operation by means of cotton and

adhesive strips. There is not the least doubt but that this imprisoning, as it were, is causing the most mischievous results, and often death. We emphatically say, keep the arm loosely clothed, put no dressing upon it, unless it is a protection shield properly made, and advise the patient to use the arm as little as possible, and keep it clean. With good Vaccine and the proper care you will have very few bad cases, unless you can find a very marked syphilitic history in your patient. Our experience has proven that syphilitic families with a decided history have shown a strong tendency to violent action.

SUMMARY OF DANGERS.

To sum up the dangers we might say that they come, first, from the improper selection of cattle; second, from the filthy condition of the establishments in which they are kept; its dangerous location; the plan of procuring Virus by pressure, and by carrying it to another apartment, after having been removed, instead of putting it on the ivory points warm, and allowing it to dry quickly. Packing it in dangerous materials for the sake of cheapness, the propagator either wanting to avoid correspondence with the consumer, or else ashamed of his goods, fails to put on his label. The druggist and physician looking for goods that cost less than ten cents a vaccination, sacrificing the lives of their patrons by buying dangerous Vaccine, or that which is not Vaccine at all, because it is sold to them at a cut rate. The druggist may keep a good article too long; it can always be exchanged for fresh without extra cost—this would be simple carelessness on the part of the dealer; the physician's retaining the goods in a vest pocket, or hot office; neglect of cleanliness in operating; want of knowledge of a proper method, and an over-anxious desire to protect the arm.

WHEN IS THE PHYSICIAN SAFE?

How shall the physician know when he is safe, and how shall he obtain the best results? First, by keeping in touch with the best propagators. Ascertain for a certainty that they have the proper kind of establishments, and exercise the proper care. Let the physician buy from a druggist upon whom he can depend, being certain that he is not getting cut-rate goods; be sure that the goods bear the label and full address of the propagator, that he may be able to correspond with the producer should he have any difficulty, either from failure or excessive action. Let him await for results of Bovine Virus from five to eight days, and never report until ten full days have elapsed, and to look with suspicion upon anything that acts on the second, third, or fourth day. In this way he can avoid many of the dangers and protect his patient, as well as help overcome the fraudulent practices of those who care not for the health of their fellow beings.

HOW TO REMEDY BY INSPECTION.

It has been suggested that the government assume control. To assume the role of propagator would, in this country, be a greater failure than it is to-day in those countries that have tried it. We are exporting Vaccine to-day, because it is pronounced superior to theirs, and I was informed this summer at Chicago by their own people that the Government Virus was not generally used by the intelligent classes. State propagation is not practicable for the one reason, if no other, that there is not sufficient demand to enable the propagator to keep up a continuous strain of propagation, or carry sufficient stock to be able to meet the demand when it arises. I would suggest a National Board of Health, composed of one member from each State Board, they to appoint inspectors from their number, whose duty it would be to thoroughly inspect every Vaccine establishment of the country, and to allow no Vaccine to be sold without a registry number, guaranteeing to the druggist, the physician, and the layman that the article he buys, uses, or has used upon himself or his children, has received the sanction of the proper authorities. Then, and not till then, can compulsory vaccination be justly enforced.

---

THE Massachusetts State Board of Health concludes, from investigations of artificial ice, that artificial processes of freezing concentrate the impurities of the water in the inner core or the portion last frozen, that the impurities are least if distilled water is used, that the number of bacteria in artificial ice is insignificant, under the prevailing methods of manufacture, and that the amount of zinc found in ice is sufficient to cause injury from its use.—*Scientific American.*

## EDITORIAL.

### THE STUFF DREAMS ARE MADE OF.

The average man spends about one-third of his entire life in dreamland, and the impressions brought from thence into normal waking life have exercised great influence on the progress of the human race. The use of the word dream is apt to result in a confusion of ideas, for the term has been applied to almost every act of cerebration, differing in any respect from the average level of mental processes; including at once that exalted condition of mind called inspiration, which enabled the seers of old to prophecy, "the old men to see visions and the young men to dream dreams," down to the reflex smile of physical comfort on the face of the sleeping infant whose mother fondly believes the angels are talking with it.

To the average human being, who is neither a prophet nor the son of a prophet, dreaming is a form of mental activity carried on during sleep when the physical being is at rest and the volitional powers held in abeyance. A recent writer* in summing up a discussion of the subject says:

"To the normal waking intellect the Sleep Land must always remain a foreign and unknown country, where the laws and customs are utterly different from those by which the waking mind lives and moves; and where even the stable verities of space and time are turned topsy-turvey. But, for all that, it is a region where there is much more movement astir than we generally imagine, and where a great deal of important business is in progress, beyond that of overhauling the animal machinery. We do not know enough of this unconscious cerebration—this commerce incessantly carried on among the brain cells—to be able to understand the full utility of such a perpetual bustle of ideas.

"Speaking very generally, one may say that during sleep the brain does an immense amount of sorting and pigeonholing of impressions received since the previous night's rest. It would appear also that some process akin to stock-taking, and the rummaging of out-of-the-

*Dr. Louis Robinson, in *North American Review*, for December, 1893.

way corners, also goes on when the judgment and will are taking holiday. Let it suffice for present purposes to say that this unconscious cerebration during sleep is undoubtedly of great utility, and is probably essential to every being with the least spark of reasoning power; and that to it, in the first place, may be attributed the phenomena of dreaming. Whether the occasional emergence of the traffic into the department of consciousness is in any way necessary to the mind in health is quite another matter, and I am inclined to think that we should, most of us, get along very well if we were never aware of dreaming throughout the whole of our lives. But we should dream, nevertheless. The evidence points conclusively to the existence of a certain amount of cerebral activity during the whole period of sleep, and there can be no doubt that the vast majority of our dreams never come to our knowledge. The storehouses of the mind are of incredible vastness. We are apt to judge of the contents of our memories by our volitional power of recollection; but the two bear as little relationship as do the treasury-vaults of a bank and the drawing power of a single depositor. Nothing that the eyes have seen, or the ears have heard, or which has once passed the turnstile of one of the other senses, is ever let go. Every face of the thousands we survey in passing through a great city, every word on every page we read, every tree and hill and stream we catch a glimpse of as we are whirled along on the railroad, every sound which vibrates on our ears from morning to night, is indelibly registered within. They may be, and most of them are, entered on the record without our knowledge, and they may remain there for a great part of a lifetime without our having any suspicion of their presence, and quite beyond the reach of our powers of recollection; but for all that they are there, and may come to light under appropriate conditions."

There are obvious difficulties to the consideration of cerebral processes of which we are totally unconscious and over which we have no volitional control, so that for all practical purposes the subject of dreams becomes limited to such cerebral impressions as are strong enough to force themselves upon consciousness during such time as the ordinary powers are inhibited by sleep. Within these limits dreaming may afford data for the profitable consideration of the psychologist, and within still narrower limits may serve to indicate to the physician obscure pathological conditions.

This is quite a reasonable supposition and indeed is generally believed by the ordinary man as a lesson from individual experience. Every one has met numberless examples of that class of dreamers whose photo-type is the man who, indulging in underdone pork, is sure to receive in sleep a visit from his ancestors. The association of ideas is the result of his personal experience, and it might not be too much to say his dream was made of underdone pork. Indeed, so firm is the conviction on the general mind that indigestion and dreaming are intimately related as cause and effect that almost every individual can, from experience, tell the stuff of which his dreams are made.

The writer quoted states elsewhere:

"Just as we are not infrequently able to localize the seat of some internal disease by taking note of the facial expression and mental disposition of a patient, so (according to the writer's experience) the cause of not a few obscure cases of insomnia can be learned from the character of the dreams which accompany the long delayed slumber. The reason is that sleep is often seriously interfered with, especially in those who have the nervous system in an irritable state from worry or overwork, by irregularities in the functions of other parts of the body which do not

attract the patient's attention when awake, but which, in that delicately balanced condition when the mind is isolated from other disturbing agencies, suffice to give the thoughts a definite direction; just as electric currents, too slight to be otherwise appreciable, will deflect the needle of a sensitive galvanometer. Thus, defective sleep very frequently results from disturbances of the digestive apparatus, or from a slight interference with the functions of the heart or lungs, of which the patient is himself quite unaware, but which will give rise to dreams of a sufficiently characteristic nature to enable an expert to diagnose the true nature of the case."

As yet however the phenomena of dreaming have been but little investigated in strictly the scientific and experimental method, and another writer, Miss Mary Whiton Calkins, in the *American Journal of Psychology*, who has made some experiments concludes that even the traditional association of nightmare and a heavy meal does not stand on very sound scientific footing. The *Medical Record* in an editorial resume of this latter article says:

"The subjects experimented upon were two in number, a man of thirty-two, and a woman of twenty-eight. The investigation was carried on for eight weeks, during which time the man had one hundred and seventy, and the woman two hundred and five dreams. They had not previously supposed themselves to be great dreamers, and the large number is accounted for by the fact that pencil and paper were kept at hand and every transient dream was at once recorded on awaking. The first point investigated was the time at which the dreams occurred. It was found that most dreams took place in the morning hours. In one case, 73.2 per cent. occurred after 4 A. M., very few on falling to sleep or before midnight. The next inquiry covered the question of the relation of the character of the dreams to the thoughts of waking life. It was found that in about fifty per cent. the character of the dream was distinctly connected with some waking thought or suggestion, while in forty per cent. some slight or vague suggestion existed.

"As to the vividness of dreams, it was found that about one-half could be classed as very vivid or decidedly vivid, so that details could be recalled and a good story written. The most vivid dreams occurred after four o'clock.

"A careful analysis of the dreams shows that during this condition the mind may exercise fairly normal activity. That is to say, the dreamer may remember correctly, imagine clearly, and think connectedly. The latter phenomenon, however, is rare. The statistics show that in the great majority of cases the dreams are associated with familiar persons and places. The subject-matter of the dreams was generally trivial, and the writer concludes that one seldom dreams of the serious problems and emotions that confront him while awake. In times of bereavement one seldom dreams of the dead. Miss Calkins considers it very improbable that the train of thought in dreams is swifter than in waking life. If she is right it destroys the credibility of a good many interesting anecdotes. Thus Napoleon is said to have dreamed of a journey, a siege, and a cannonading, and awoke while some explosion was still reverberating.

"Curiously enough, some attention is given to the subject of prophetic dreams and telepathy. While viewing the subject with commendable scepticism, the writer cites several dreams which appear to have a certain previsual or telepathic character. The relationship of certain diseases to dreams is a matter of especial interest to the physician; but here he must himself take up the subject and carry out investigations."

It will thus be seen that the subject of dreams presents an unexplored realm for the researcher, though one of interest greater, perhaps, to the psychologist than to the practicing physician, and promising richer rewards to the student of metaphysics than to the doctor who can find scarcely time enough to meet the requirements of his duties as a member of a life-saving service.

# ABSTRACTS.

## COLD HANDS AND FEET.*

WM. H. FLINT, M. D.

Many children, though apparently in very fair health, habitually have cold hands and feet. This is, indeed, such a common occurence that, in many instances, it hardly excites the attention of those to whom the care of the children is entrusted. Even if it does strike the observer as rather unsual, it is generally dismissed with casual comment, as of no particular importance. This is, in the opinion of the writer, a serious mistake, since the existence of persistently cold hands and feet seems to him the infallible index of disorder in the bodily mechanism, or of deterioration in the vital fluids, which should receive prompt attention and which, if disregarded, may lead to graver pathological conditions. This remark does not apply, of course, to those cases in which the extremities have been only temporarily chilled by exposure to cold and to moisture, and in which the natural temperature is easily restored by the agency of warmth, of dry air and of friction.

There are several unatural conditions capable of giving rise to cold hands and feet, and some of these leading factors are here tabulated in order that *Babyhood's* readers may more easily ascertain the causes of cold extremities and may, if possible, remove them, with the view to the prevention of actual disease. These conditions are: 1. Indigestion; 2. Nervous Excitability; 3. Imperfect Circulation; 4. Impure Blood. In order that the reader may readily understand the physiological mechanism by which the first two causes produce their effects, it is proper to recall the facts that the warmth of a part will depend, other things being equal, upon the amount of blood present in its tissues; and that the quantity of blood sent to the various organs is determined by a delicate double system of nerves, which regulate the calibre of the blood vessels and which are themselves controlled by nerve centers located in the brain and in the spinal cord. One of these sets of nerves contracts the muscles in the walls of the small arteries, thus partially shutting off the blood from the vessels, while the other set dilates the arteries. If the latter nerves gain control of the arteries, in any part of the body, these vessels increase greatly in capacity, and a large quantity of blood passes into them and into the corresponding veins, the surface soon becoming red and warm. An example of this physiological act is seen in blushing. Sudden pallor is, on the other hand, due to the preponderating influence of those nerves whose duty it is to contract the blood vessels.

Now, *indigestion*, the first cause of cold hands and feet mentioned in our list, probably produces its effect upon the extremities by stimulating the centers which control the vessel-contracting nerves. It is assumed that this may be accomplished either by the irritation of the mucous membrane of the stomach and of the intestines, through coarse or undigested foods, and by the stimulating products of unnatural fermentations, or by the absorption into the blood of these same irritating substances and of poisons emanating from the bacteria which are instrumental in producing fermentation of the undigested foods.

While indigestion is probably the most frequent cause of cold extremities, it is, perhaps, the most easily removed of the causes enumerated above. The writer has repeatedly insisted, elsewhere in *Babyhood's* pages, upon the necessity of checking digestive disturbance speedily, lest they lead on to actual digestive and constitutional disease. This warning he begs

* *Babyhood*, February, 1894.

to repeat and to emphasize in this connection. When, therefore, cold feet and hands betray the probable presence of disturbed, let us spare no means, whether dietetic, hygienic or medicinal, to remove any existing dyspeptic ailments before they lead to organic disease.

In cases of cold extremities from any cause, temporary relief may be afforded, by various means, while the real source of the trouble is being discovered and remedied. Much good may be accomplished by properly protecting the hands and feet. Woolen or silk stockings should be worn during the fall, winter and spring months, and should be changed several times daily, in order that the perspiration retained in the stockings be not long kept in contact with the feet. If this precaution be neglected, evaporating from the damp stockings soon chills the feet, the effect being the same as if they had purposely been enveloped in moist cloths. Brisk friction, with the hands and with dry towels, employed at the time when the stockings are changed, will greatly assist the circulation in the feet, thus promoting warmth and comfort. The shoes should be so large as not to pinch the foot, and the soles and uppers should be thick and firm. The hands ought to be protected by woolen mittent or gloves, which should be well dried, at the fire, from time to time.

*Nervous Excitability* may give rise to cold extremities. The nervous system is so delicately balanced and so susceptible to slight impressions, in this class of cases, that little shocks and irritations of the controlling nerve centers are constantly produced by influences incapable of exciting such responses in those children whose natures are more phlegmatic or apathetic. Emotions, whether of joy, of sorrow, of anger, of pleasure or of pain, may suffice, in these patients, to set the vessel-contracting nerves into action, by which the surface is deprived of blood and depressed in temperature. Nervous susceptibility, of such a high grade as has just been described, should be removed by proper management and treatment, lest it lead into functional or organic nervous disease. The cause of such exaggerated sensibility, on the part of the nerves, may be deeply hidden and may require the aid of the family physician for its discovery and its removal.

*Imperfect Circulation* may be responsible for persistent coldness of the hands and feet. The heart's action is not strong enough to propel the blood into the extremities with sufficient force and rapidity to keep them adequately warmed, the hands and feet being more remote from the central organ of the circulation than any other parts of the upper and lower members. Given this origin of the symptom we are considering, it may be of great importance for the future physical welfare of the child that the heart's action be strengthened, and that any unsuspected cause for this weakness of the circulation be ferreted out and, if possible, removed. This is true because, without healthy heart action, perfect growth and nutrition are impossible, and because heart weakness may imperceptibly develop into actual heart disease.

*Diseased Condition of the Blood* may also occasion coldness of the hands and feet. The warmth of the body (called vital heat), as well as its growth and repair, is chiefly due to oxidation occurring in all the tissues. The oxygen required for this all-important chemical process is conveyed to the tissues by the red corpuscles of the blood. If these corpuscles are diseased, so that they cannot act as efficient oxygen carriers, or if they are not sufficiently numerous to convey an adequate supply of oxygen, normal oxidation cannot take place, temperature is reduced below the normal point, and the tissues suffer from innutrition.

If this condition of affairs is allowed to continue, the child's growth must be stunted and the patient is also exposed to graver dangers from the occurrence of any constitutional disease than he would be were his blood and his nutrition in a healthy state. It is natural that coldness of the surface, due to depreciation in the quality of the blood, should show itself most strikingly in the extremities, for they are more exposed to refrigeration than the more warmly covered trunk and members. They are, moreover, farthest from the heart, the action of which is apt to be impaired whenever the blood is disordered.

In conclusion, the writer begs his readers not to neglect this apparently trivial symptom of cold hands and feet, but, being forewarned by its appearance, to seek out and remove its cause, in order that their children's natural growth and development may be promoted and that possible disease may be averted.

## APPENDICITIS.

In a lengthy article on Appendicitis in *Mathews' Medical Quarterly*, Dr. F. Byron Robinson draws the following conclusions:

1. The diagnosis of appendicitis rests on pain and tenderness in the right iliac fossa, vomiting, temperature and tympanitis. A tumor may be found in about one-third of the cases.

2. The *pain* is due to an appendicular peristalsis. It may arise from perforation. It is appendicular colic, or may be due to inflammatory invasion. The constipation is not mechanical, but *reflex*. The tympanitis is due to reflex paralysis of the bowel. The vomiting is reflex. The lameness is due to pressure on the lumbar plexus. The sudden cessation of pain is often due to the expulsion of the body into the cæcum. Adhesions may induce pain.

3. The infective invasion of appendicitis may induce œdema, hemorrhage or phlibitis into the right iliac fossa. I know of an embolus going to the liver after operation and infecting it, killing the patient.

4. The appendix resembles the tonsils, and is subject to similar temporary inflammations at the same ages in both sexes. It is lymphatic in structure. Its glandular (lymphoid) element is large.

5. About one-half of appendicitis is catarrhal or parietal, and should not have surgical interference. Relapsing appendicitis is not a dangerous malady. All suppurative and perforative cases of appendicitis should be operated on as soon as diagnosed.

6. My experience with appendicitis in children is, that it is very progressive and very fatal, and should be operated on as soon as reasonably diagnosed. It invades rapidly in children on account of its large lymphatic constituents.

7. Males have appendicitis four times as often as females.

8. The age of appendicitis is the same in both sexes—from ten to thirty years mainly.

9. The chief cause of appendicitis lies in the small size of the appendicular mouth. The mouth is guarded by a valve of mucus membrane (Gerluch's). With a small mouth objects insinuate themselves through, but irritation of the foreign body on the mucous membrane of the appendix induces it to swell and close the mouth so that the foreign body is unable to get out. It seems to the author that Gerlach's valve is larger in men than in women.

10. The vermiform appendix is the most variable organ in the body, viz., in length, situation and peritoneal environments. Hence its pathological conditions vary in position and environments.

11. Many hundreds of autopsies show that from fifteen to twenty per cent. has had appendicitis and died of other diseases. The periappendicular adhesions remain.

12. Anatomical description of the appendico-cæcal region has varied from the beginning until now. The main statement which can be made at present is that the cæcum is entirely covered by peritoneum, while the appendix always originally had a mesentery. The peritoneal attachments vary because the rapidly-growing cæcum steals away the peritoneal covering from the atrophying appendix.

13. A perforation of the appendix will nearly always open into the peritoneal cavity, but it may open into the post-cæcal areolar tissue. In this case it will open between the layers of the meso-appendix and pass over the upper border of the cæcal peritoneal covering.

14. Microbes play the chief role in appendicitis. They multiply rapidly when the appendicular mouth is closed and the appendicular secretion is changed, producing perforation and disturbed circulation.

15. The result of the closure of the appendicular mouth is irritation. The glandular secretion becomes excessive and disproportionate from the irritation of the foreign body and microbes. Deranged and fermenting secretion, confined, aids downward progress. Circulation is deranged; the veins and lymphatics become overfilled, œdema results, local or general necrosis (or gangrene) follows, and a perforation of the appendix supervenes, which induces local or general peritonitis. If limited by exudates the peritonitis will be local. But peritonitis and exudates can and are produced by microbes or their products (ptomaines) penetrating the appendicular wall, leaving no visible perforation.

16. The pain is felt in the right iliac fossa in about half the cases, and the other half feel the pain in the abdominal cavity—not localized. In general most

abdominal pain is felt around the umbilicus, that is over the abdominal brain. There is frequently a referred pain in appendicitis. McBurney's point is useless and untrustworthy.

17. In my experience in young women, frequent micturition often accompanies appendicitis. The abscess is more likely to move in the pelvis than in man. It may be due to the appendix being over the brim of the more spacious female pelvis more frequently than in males.

18. Bowel obstruction and constipation in appendicitis is reflex, not mechanical.

19. Vomiting is due to reflex irritation carried up the superior mesenteric plexes to the abdominal brain, where it is reorganized and emitted to the stomach. Every viscus suffers from reflex irritation, especially those supplied by a large plexus of nerves containing many nerve strands, as for example, (*a*) the stomach, (*b*) the small intestine, (*c*) the heart, (*d*) the kidney, (*e*) the spleen, (*f*) genito-urinary organs, (*g*) lungs.

20. The tenderness in the right iliac fossa is not uniform in location, but exists wherever the pathological appendix happens to lie.

21. The rise of temperature is due to toxic substances in the blood—infection. A subnormal temperature may be due to overwhelming the system with the toxic substance. It seems that violent irritation of a sympathetic plexus of nerve can raise or lower temperature.

22. Perforation of the appendix infects the pelvic organs of women, and the tubal and ovarian infections infect the appendix.

23. Probably ninety-five per cent. of the diseases about the cæcal region arises in the appendix.

24. In regard to operation in appendicitis it may be asserted that a low mortality in itself does not justify any surgical procedure.

25. Cases of acute appendicular perforation with diffuse peritonitis should be operated on, though recently every case is fatal. Out of every two hundred autopsies on dogs killed or dying after I had performed abdominal experimental procedure, I found no dog survive general peritonitis. I know of two surgeons of this city (Chicago) who have operated on seventeen cases of diffuse peritonitis following appendicitis, and every case died.

26. Localized abscess in the cæcal region should be incised, and if it be not too dangerous for the patient, the appendix should be ablated.

27. Subjects of severe recurrent appendicitis should be operated on for comfort and utility of the patient.

28. The cardinal principal in the operation is to manipulate the viscera as little as possible. If one evacuates an abscess in the cæcal region it seems unwise to waste time or manipulate very much in order to get the appendix; simply irrigate and drain with gauze. It is not perfect surgery, but it is *safe* surgery, which is really most perfect to the patient.

29. The various forms of appendicitis give varied results in operation. The diffuse peritonitic form gives almost one hundred per cent. mortality; the recurrent form has some eight per cent. fatality; the general mortality for appendicular operation will be not far from fifteen per cent., except in the case of individual surgeons who operate on almost every occasion. It would appear that the surgical mortality is over fifteen per cent., while from the best sources that about eighty-five to ninety per cent. recovers without operation. At this rate nature has a less mortality than the art of surgery.

30. Treves says that eighty per cent. of cases of appendicitis get well spontaneously. Talamon says that ninety per cent. get well with a certainty with no operation. Guttman treated medically one hundred cases, and four died.

31. The foreign body in the appendix is generally dried feces mixed with calcium salts, and not some solid body, so that, so far as our present knowledge goes, physicians cannot claim that swallowing cherry stones, grape seeds or fruit pips, etc., tends to induce appendicitis. No doubt some form of indigestion or colitis precedes many cases.

32. Observation and practice seem to teach less surgery on the appendix than formerly. Judgment is becoming more accurate as to what cases demand operation. Autopsies and pathology would seem to limit operative work more and more. Post-mortems are telling the more exact story of frequent appendicular lesions from which the patient recovered. The following of conservative but representative men like Treves, Guttman, Talamon, Fenges, and many others, is increasing. Yet reasonable surgery will always hold an important place in appendicular diseases, for the appendix is a useless organ.

## THE ORIGINAL OF SHERLOCK HOLMES.

It was, therefore, with great satisfaction that the reader of Dr. Conan Doyle's fascinating stories learned some time since, from the author of his being, that Sherlock Holmes was indeed founded on fact and drawn from life, and that the model for him had been a professor in the medical college in which Dr. Doyle studied. This gentleman has been the object of an extensive and pardonable popular curiosity. He is Dr Joseph Bell, of the Royal Infirmary of Edinburgh. He studied at the famous University of Edinburgh, took his degree at twenty-two, was for two years assistant demonstrator of anatomy in the university, then became house surgeon, and latterly consulting surgeon.

It is evident that the medical profession offers peculiar advantages for the development of the faculty of observation, which, indeed, is as helpful and indispensable to an ideal doctor as to an ideal detective. Diagonis is, indeed, largely detective work, and those who have the good fortune to be the patients of a "born doctor," when they had the misfortunes to be patients at all, often have occasion for astonishment at a knowledge of their condition that seems to them like clairvoyance, but in truth the result of a natural faculty for observation assiduously cultivated. It is evident that the original Sherlock Holmes has the faculty in an eniment degree.

A reporter of the *Paul Mall Gazzette* has had, and related for his paper, a highly interesting interview with the original of Sherlock Holmes. It appears that Dr. Bell has made use of his remarkable faculty not merely in the line of his profession and for the astonishment of his acquaintances, but that it has frequently, been employed in actual detective work. and in furtherance of the ends of justicel As might be expected, he has paid special attention to medical jurisprudence. The crown retains in Edinburgh a regular medical adviser in criminal cases, and this medical adviser has for some twenty years been in the habit of enlisting the services of Dr. Bell, although in these cases he has merely been retained as an expert, and has no official connection with the crown. The reporter who visited Dr. Bell was in Edinburgh to report the Ardlamont murder trial, which has attracted comparatively little attention in this country, but has excited a great and widespread interest in England and Scotland; and in this case Dr. Bell has been retained as an expert adviser for the prosecution. While he declined to give any reminiscences of his detective work that had not already been made public, he declared that whatever deductions he had been able to make that had been of service to the authorities had been "simple and commonplace." They had come from the habit he himself had formed and had tried to inculcate upon all his scholars—Conan Doyle among them—the habit of paying attention to what are commonly dismissed as unimportant things. "I always impressed over and over again the vast importance of little distinctions, the endless significance of the trifles." To what important results this habit may lead is illustrated in the facts of Dr. Bell's career, as well as in Dr. Doyle's action founded on those facts. One illustration of it is striking enough to be well worth giving in Dr. Bell's own reported words:

"This one struck me as funny at the time. A man walked into the room where I was instructing the students, and his case seemed to be a very simple one. I was talking about what was wrong with him. 'Of course, gentleman,' I happened to say, 'he has been a soldier in a Highland regiment, and probably a bandsman.' I pointed out the swagger in his walk, suggestive of the piper; while his shortness told that if he had been a soldier, it was probably as a bandsman. In fact, he had the whole appearance of a man in one of the Highland regiments. The man turned out to be nothing but a shoemaker, and said he had never been in the army in his life. This was rather a floorer; but being absolutely certain I was right, and seeing that something was up, I did a pretty cool thing. I told two of the strongest clerks, or dressers, to remove the man to a side room, and to detain him till I came. I went and had him stripped. Under the left breast I instantly detected a little blue 'D' branded on his skin. He was a deserter. That was how they used to mark them in the Crimean days, and later, although it is not permitted now. Of course the reason of his evasion was at once clear."

After one knows that Sherlock Holmes

is not entirely the creature of the novelist's imagination, but that his qualities are drawn from life, many readers must be incited to develop those qualities in themselves. In the interview from which we have quoted, Dr. Bell says, very truly and suggestively:

"I should just like to say this about my friend Doyle's stories, that I believe they have inculcated in the general public a new source of interest—the kind of interest created by Richard Jefferies and the 'Son of the Marshes.' They make many a fellow who has before felt very little interest in his life and daily surroundings think that, after all, there may be much more in life if he keeps his eyes open than he had ever dreamed of in his philosophy. There is a problem, a whole game of chess, in many a little street incident or trifling occurence if one once learns how to make the moves."—From *Harper's Weekly*.

### Professor John Tyndall.

Now, Tyndall was one of those men who bear a large share in the actual technical work of such great discoveries. But it is hard to put one's finger upon any single point easily to be apprehended by the ordinary intelligence. He taught us much, for example, about the way radiant heat is propagated through the atmosphere; about the objects which are, so to speak, opaque or transparent to it; about the effects it produces on the surface of our planet. He taught us much about how glaciers are formed, move, and are retarded, break into crevasses and freeze together again, compress themselves through gorges, or spread themselves, though solid, into lake-like expansions; and he did more towards explaining these singular phenomena than any other observer. His contributions to the sciences of light, of sound, of electricity, of magnetism, of heat, and even of biology (so far as regards the diffusion of the germs of minute organisms), are all of them most valuable. He was a fellow-worker in the triumph of evolutionism and of just and sound views about energy. But for the most part he led up towards those great developments in physical and electrical knowledge which have not yet been made and towards practical inventions which have not yet been invented. This sort of work is the most valuable of all, but it is often the most inglorious. So it comes about that Tyndall, who was himself a most careful, accurate and patient investigator, was best known as a popular expounder and an almost sensational orator. He would not have been so famous if he had not superadded Belfast addresses and Royal Institutional lectures to his real work in the laboratory and on the mountain.—From a Character Sketch of Professor Tyndall, by Grant Allen, in the February *Review of Reviews*.

---

The Dangerous Communion Cup meets increasing opposition. Doctors should agitate the subject, like Dr. A. J. Longfellow of the M.E. Church in Fostoria, Ohio, who moved the following resolution: "Resolved, That the church purchase four hundred little wine-glasses and each communicant receive the wine out of a glass that no other person has used, and the bread passed on baskets or plates, and that it be not handled or broken by the preacher." This is a good second to the movement against the still more dangerous incident of alcohol in the communion cup.

---

Chlorine in liquid form is now being manufactured by Messrs. Pechiney & Co., of Salindres, in France, and at the Rheinania Works, at Rheinan, near Mannheim, in Germany. The gas is liquefied by subjecting it to a pressure of 50 atmospheres (750 pounds) to the square inch and stored in strong iron vessels holding 120 pounds each. It is delivered from these vessels either in the liquid or gaseous form, and can be used in bleaching. It is said to be as economical in use as bleaching powder, while it has some advantage over that product.—*Scientific American*.

### Check.

The man who tries to take advantage of the ignorance of another occasionally gets a Roland for his Oliver. A Boston man once, in England, seeing a laborer digging flints out of chalk, pompously asked him if he thought they grew.

"Sure," was the reply, "I know they do."

"Then put some flint on a table, and see how much it grows in a year."

"And you, sir," said the laborer, "put a potato on the table, and see how much it grows in a year."—From the "Editor's Drawer," in *Harper's Magazine* for February.

# SOCIETY REPORTS.

## THE LOUISVILLE CLINICAL SOCIETY.

*January 16th, 1894.*

### REMOVAL OF BULLET FROM THIGH OF A MAN WHO HAD CARRIED IT SINCE THE BATTLE OF SHILOH—32 YEARS.

DR. W. O. ROBERTS: Last week a gentleman fifty-two years of age, consulted me with a tumor in the popliteal space of the right leg. The tumor was about the size of a guinea-egg, located just at the outer side of the inner ham strings. He furnished the following history: At the battle of Shiloh while in a stooping position to fire, he was struck by a shot just above the knee. The bullet as he said ranged upward; the wound was probed some six or eight inches, according to his statement, without finding the ball. He was in the hospital over six months before the fistulous tract closed. He then left the hospital and went back to his command, and soon after re-entering the service while under march his leg became very sore, considerably swollen, he became very lame and was sent back to the hospital. At this time he was in the hospital at Atlanta, Ga., where he was seen by Dr. Westmoreland. Soon after the doctor saw him, he made a free incision in the upper part of the thigh, about four to six inches above the point of entrance of the bullet, and removed quite a quantity of pus and broken down tissue, but did not find the ball. This wound was slow in healing, but after it healed he had no further trouble until a few months ago, when he began to complain of stiffness about the muscles of the back part of the thigh, pain just above the popliteal space and tenderness on pressure. He noticed in sitting down that part of the limb which came in contact with the seat gave him great discomfort, and only about three or four weeks before I saw him he detected in the location I have mentioned, this tumor. I cut down upon it and removed the bullet which I exhibit. You will observe the peculiar shape of the ball. One point of interest is that there is a phosphatic deposit on one side of the bullet.

#### DISCUSSION

DR, J. W. IRWIN: This is rather a singular coincidence. Last Friday a gentleman came in my office complaining of loss of memory, and pain in the back of his head extending down his neck, which had been in existence for ten years. He sought relief chiefly on account of his memory. He had been a private in the Northern Army, and had received a shot at the battle of Shiloh; the ball had entered his face along side of the wing of the nose just above the alveolar process of the gums. The bullet had never been found. I made an examination of the case and found along side of the origin of the ligamentum nucha some enlargement, and, upon closer investigation, I found that the bullet was encapsulated there. I suggested that the bullet should be removed. He was not then prepared to have the operation done. He went home and I have not heard from him since, but what course this bullet took I cannot tell, anyway it had caused loss of memory and had a very decided effect upon the intellectual faculties. It had lodged in the back part of the neck near the first dorsal vertebra.

DR. A. M. VANCE: The case reported by Dr. Roberts is certainly a very interesting one. I cannot believe that the tract explored by the surgeons could have been the tract of the bullet, it must have been due to clothing or something else. This bullet could not have gotten in the position where Dr. Roberts found it after having gone up the thigh. The case illustrates what a false guide a probe is often times in gun shot wounds, and how it may go in almost any direction after it gets into the cellular tissue. I believe that the bullet passed directly through the man's thigh in a backward direction, and finally settled down in the position Dr. Roberts found it.

DR. I. N. BLOOM: I would like to inquire whether any practical results have been obtained by probing for bullets with the electrical apparatus such as was used in Garfield's case?

DR. A. M. VANCE: Several new instruments are on the tapis for this purpose just now, but what practical results have been brought about I do not know.

DR. T. P. SATTERWHITE: The case is very interesting and shows what nature does in encapsulating foreign bodies. I remember several year ago removing from a man's arm a piece of glass about ½ inch long, which had remained in the arm for twenty years without producing any disturbance, until a few months before it was removed.

DR. P. GUNTERMANN: When I was a boy 15 or 16 years of age, I remember that there was a retired Major in our little town, who had been a soldier under Napoleon, having passed through all the wars, had been to Russia, the Battle of Waterloo, etc. He

took great pride in exhibiting his right leg in which there were five bullets. These bullets were of the old fashioned large variety, and could be distinctly felt. He had several inducements to have them taken out but he refused, stating that he "wanted to take them with him," and he did carry them with him to the grave. They never gave him any particular trouble. He was not a very large man, about the ordinary size and weight. I simply mention the case to show how long bullets may remain in the tissues without giving rise to any serious trouble. It was forty years after receiving these bullets in his leg that the old Major died.

---

DOUBLE HYDROSALPINX AND CYSTIC OVARIES.

DR. L. S. MCMURTY: I present for examination a specimen of hydrosalpinx and cystic ovaries. The symptoms in the case were menstrual irregularity, general pelvic pain and irritation of rectum and bladder with sterility. The patient is about thirty-two years of age; she has one child, six years old. Two years ago she consulted a surgeon who operated for laceration of the uterine cervix without any improvement of her condition. In making a vaginal examination I detected a mass in each lateral pelvic space. The abdomen was opened, and the specimens which I exhibit removed. She is making an easy recovery. The operation was performed ten days ago. The Fallopian tubes are as large as average size sweet potatoes, and so distended with serum that they would readily have broken and emptied into the peritoneum. The ovaries are each converted into a monocyst. By careful manipulation I succeeded in removing them without rupture.

---

DR. J. W. IRWIN, read a paper entitled,

THE DANGERS OF INFECTION BY PERSONAL CONTACT WITH DISEASES NOT REGARDED AS ACTIVELY CONTAGIOUS OR INFECTIOUS.

See page 232.

DISCUSSION

DR. T. P. SATTERWHITE: I think it is very well that persons who are invalids should not sleep with any one. I agree perfectly with Dr. Irwin in that particular. I see no harm, though, for two healthy persons to sleep in the same bed. It is a very common thing now for a man and wife to occupy separate beds.

DR. I. N. BLOOM: In France, Austria, Italy, and Northern Germany it is very rare for more than one person to occupy the same bed. The beds are single and placed some distance apart. In Vienna it is very difficult to find a large bed. What they call a large bed there is a canopy affair not nearly as wide as the double beds in this country, and only designed for one person. As a rule they only have a bed three feet wide, the husband and wife each having his or her own bed.

I believe a reform in this matter would be a decided benefit to people generally.

DR. J. M. KRIM: There is no question in my mind about consumption being contracted in the way suggested by Dr. Irwin: I remember a case where a man died of consumption; his wife nursed him until he died. She married again about six months afterward, and died of consumption eight months later. Her second husband also died of consumption. No predisposition by heredity or otherwise could be traced in either of these cases, and there can be no reasonable doubt but infection occurred in the way Dr. Irwin has stated.

DR. J. W. IRWIN: I would like to ask if anybody has had any experience with the examination of air respired from the lungs of consumptives, and in what way the disease is transmitted, whether by absolute contact with the lips, or through the respired air, or both?

DR. P. F. BARBOUR: We cannot deny that it might be by both. I should think though, it would be more likely to occur through the inhaled air.

DR. J. W. IRWIN: But there is no very definite record of the germs of consumption having been found in the respired air from the lungs of persons suffering from that disease.

DR. C. G. LUCAS: I think it has been proven by experiments made by a German observer (whose name I have forgotten) that the tubercle bacillus is transmitted through the medium of the respired air. In these experiments guinea-pigs were suspended in a cage before tuberculous cattle, and in a very short time evidence of tuberculosis were found in the guinea-pigs.

DR. J. W. IRWIN: I asked that question because in a former discussion of this subject the point was raised that the bacillus of consumption had never been found in the respired air from the lungs of persons suffering from that disease. The literature on the subject is very meagre, and there is some doubt as to whether the bacillus has ever been found in the respired air or not. But if it has not been found, that does not prove that the respired air does not contain the germs of the disease. Experiments with guinea-pigs are not conclusive from the very fact that even their close confinement may bring on wasting diseases. They are the easiest of all animals that we know anything about to contract disease.

Some years ago a series of experiments were made upon dogs which were confined in the manner spoken of by Dr. Lucas, by taking the sputa from consumptives and diluting it and putting it into a spraying apparatus and once a day spraying the dogs with this diluted sputa. The dogs were strong healthy animals furnished by a pound keeper. On the twenty-seventh day after the spraying began the first dog was killed, and he was found to have a number of tubercles in his lungs. On the thirty-fifth day the second dog was killed, and he was found to be still more affected. The third dog was killed in two months and both lungs were infiltrated with tubercular deposits. That was an experiment to show the contagiousness of consumption through the sputa in a diluted form, rather than through the respired air. Two other dogs were sprayed with a solution of calf brains in the same way and under the same confinement, and they were killed in two and four months after the spraying began, and no trace of disease of any kind was found in them. When we come to consider all the facts and all the circumstances between the husband and wife, we cannot attribute it altogether to respired air, in that the husband and wife are so likely to kiss each other and the germs may find their way to the lips and in this way they may contract the disease rather than from or through the respired air. Be that as it may the weight of authority seems to point to the expectoration as the most dangerous source from whence the disease comes to those in close contact with it. That the consumptive expectorates and that is deposited on the ground, on the floor or on the bed, that it dries and it is stirred up in the dust and it is inhaled. The germs of the disease in this way enter the lung rather than through the respired air from the consumptive. Some fallacy seems to me to exist in this statement, in that the husband (when the wife is the subject of consumption) is the one who contracts the disease (or vice versa) rather than other members of the family and the one most likely to contract the disease would be the chambermaid who sweeps the apartment, for we all know what a cloud of dust even a single sweeping will cause, and the dangers of inhaling the poisonous products of the expectoration from that source to the chambermaid would seem to me to be very much greater than the inhaling of the dust in a much lesser way by the husband or the wife. I rather think we have the principle cause in personal contact together with the inhalation, and while the germs have not been reported as found in the atmosphere, I am still inclined to the belief that they may yet be found in it and in view of all the facts that whether it be the germs, or whether it be the toxalbumens or other poisonous products due to the waste of tissue coming from the body, the infection is due to personal contact with the consumptive, and those coming in closest contact are in the greatest danger and are the first to become affected; that sweeping the room is not dangerous to the person sweeping or to those coming in contact with the dust which rises, as personal contact with the patient suffering from the disease.

DR. P. F. BARBOUR: There is one point in this connection that might be investigated, that is whether the husband or children are more liable to contagion.

Of course the nursing child is predisposed to tuberculosis, in fact the tubercle bacillus has been found in the milk of the nursing mother. But children past beyond that age playing about the room for instance, inhaling the dust from sweeping, etc., would they not be as liable to infection as the husband or wife?

DR. J. W. IRWIN: Investigations have been made in that line, and results go to show that the husband or wife as the case may be, is very much more liable to contract the disease than any other member of the family.

DR. A. M. VANCE: I saw a statement some time ago which showed that more widows and widowers died of consumption in proportion to numbers, than any other class of people; proving that those who have been previously healthy, and the wives or husbands of consumptives die in vastly greater proportions than the ordinary populace.

---

CONTINUED REPORT — INTENSE HEADACHE FOLLOWING A BLOW; OPERATION.

DR. W. O. ROBERTS: I would like to continue the report of a case which I presented to this society some little time ago, the man who had been struck on the head nine years ago and had been suffering with the most intense headache nearly ever since. This headache steadily increased in severity, and I had him admitted to the City Hospital. The night before I operated upon him, it required a grain of morphine hypodermatically to quiet him. At my clinic I simply raised a horse-shoe flap including the cicatrix in it; I found no trouble with the skull, so replaced the flap, and strange to say he has been entirely relieved of all distressing symptoms, headache, etc., and he is now working at the hospital in the capacity of night nurse.

---

EXTRA-GENITAL CHANCRE.

DR. I. N. BLOOM: Some time ago I read a paper before a meeting of this society upon the subject of "Extra-Genital Chancres." I have recently had a very interesting case of

this character, which was referred to me by a prominent surgeon of this city. The patient is a lady forty-five years of age; she separated from her husband and has not had sexual intercourse for fourteen years. She came to me with an undoubted syphilitic eruption all over her body. There were characteristic scabs in the hair, and slight glandular enlargements. The case was so plain that I made a positive diagnosis at first sight. Her first visit was in the evening, and as the light was not very good, I requested her to come back the next day. On her first visit I made a very close examination in an endeavor to discover the initial lesion or its site, but was unsuccessful and did not find it the next day. I told her what was the matter with her, and that I was very anxious to know how she contracted it. On the third visit, five days after I first saw her, she called my attention to a sore at the site of the wisdom tooth which was wanting in this case, on the right side. She told me that this sore had been there for a number of weeks, just how long she did not know. Then later she informed me that there was a gentleman whom she had known all her life, who had been in the habit of kissing her, and she found out afterward that this man had syphilis. I am satisfied that the point of infection was posterior to the last molar tooth, and the case I am reporting is a chancre. The woman afterward developed mucous patches in the vagina which are sufficiently rare to deserve notice. The case to me is a very interesting one on account of the unusual site of the chancre, and that this is the point of infection I think we have positive proof. I will also state that the glandular enlargement was very slight, which is contrary to the rule. Usually in cases of chancre about the head you will find very decided glandular enlargement.

DISCUSSION.

DR. J. W. IRWIN: The case reported is a very interesting one; the history of it, however, is defective. I do not believe that the case was one of contagion through the gum; contagion through the gum would not necessarily be followed by mucous patches in the vagina. A chancre on the lips would not necessarily be followed by this condition of the vagina, and, I doubt if there is a case on record of this character, where the history of the case has been clinically truthfully obtained. Of course these patients always deny anything like carnal intercourse. I cannot believe that the lady told the truth.

DR. I. N. BLOOM: It is quite a serious matter to be told that your judgment in the case of a woman is wrong, when you yourself know the woman and know of her and form your ideas as to whether she is telling the truth or not; but I should think it would be a great deal more difficult for a person who has never seen her to make any such assertion. In a case of this kind I think the doctor who makes the examination by close questioning can usually tell whether the truth is being told or not. This patient was a very intelligent women, and I believe she was sincere in what she said, as she seemed very anxious herself to find out how infection could have occurred. As for mucous patches necessarily following a chancre, that is a mistake; mucous patches need not necessarily follow a chancre anywhere. I believe it is the exception rather than the rule, that mucous patches are found in any situation following chancre. I have seen several cases where there was an undoubted characteristic chancre, which was followed by a very slight eruption and nothing else. One of the cases I have had under observation for three years, and no further sign of syphilitic disease has manifested itself. Mucous patches are just as liable to occur in the vagina if the chancre appears on the tongue as if it makes its appearance on the genitals; in other words a chancre may be followed by its characteristic sequelæ, no matter where it occurs. So that no argument can be deduced as far as the criticism of Dr. Irwin is concerned; I fail to see where he has established a single point, or that any idea of the diagnosis can be obtained from either side—of the mucous patches wherever they might occur, or from his judgment as to whether the lady was telling the truth. We are bound to be governed to a certain extent in these cases by the impression that the patient give us. A person who can read character thoroughly is, of course, able to form a better judgment than those who cannot. While I am skeptical about a great many people, and frequently listen and disbelieve patients, in this case I am thoroughly convinced that the woman was telling the truth, and that the point of infection was the situation I have mentioned. The sore back of the gums was undoubtedly a chancre, and the eruption was certainly syphilitic.

---

REPORT OF SEVEN CASES OF ANTERIOR VENTRAL FIXATION OF THE UTERUS.

DR. W. H. WATHEN: There are various methods of treating retro-placed uteri with and without operation. Usually these cases are treated by a properly adjusted pessary, etc., which may give temporary or permanent relief, but there are cases where the pessary does no good and causes pain; and where there is inflammation of the pelvic structures, or adhesions, its use is dangerous. Where the uterus is not held down by adhesions, and the tubes and ovaries are healthy there are very few cases where a laparotomy for ventral fixation of the uterus

would be justifiable. But we cannot always positively decide that there is no disease of ovaries or tubes, and that the uterus is free of adhesions. In laparotomy work adhesions are often found that could not be diagnosed in previous examinations. Where there are no adhesions, the Alexander operation has been followed by good results in well selected cases, where the operation was correctly done and a properly adjusted pessary worn for several months; but this operation was contra-indicated in the cases I wish to report.

CASE 1.—I operated two weeks ago upon Miss M., of Indiana, aged thirty, who had been an invalid for many years and had ¼ grain of morphine hypodermatically, frequently repeated. Menstruation had been very painful for ten years. Her nutrition was poor and her inhibitory powers nearly destroyed. In a digital and bimanual examination I found the uterus retro-flexed and adherent, but could detect no disease of the ovaries or tubes. When the abdomen was opened, the uterus was found adherent to the pouch of Douglas, and the ovaries were so cirrhotic that there was but little healthy tissue. One tube was inflamed, but no pus was found in it. The ovaries were not larger than the end of my little finger. The adhesions were separated and the tubes and ovaries removed. The uterus was then fastened to the anterior wall at the lower point of the incision by two silk worm gut sutures introduced through the entire thickness of the abdominal wall and into the uterine tissue, under the peritoneal layer including one inch transversely, one suture being introduced on a level with the tubes and the other half inch higher in the fundus. Before tying the sutures I sacrified superficially that part of the uterus that came in contact with the abdominal wall. The woman had no untoward symptom, took no morphia after three days, suffers no pain, is out of bed, says she is well, and I feel sure will be entirely restored to health. The uterus is firmly adherent to the abdominal wall.

CASE 2.—Mrs. C., from Indiana, was operated upon three years ago; her uterus is still held in position. She became pregnant some months after the operation, and induced an abortion at the fifth month? She again became pregnant and the child was delivered at term. She is now well and her uterus adheres to the wall. In this case I operated by introducing silver wires through the walls upon each side of the wound, carrying them through the broad ligaments, including the round ligaments, but not the Fallopian tubes.

CASE 3.—A little over two years ago I operated upon Miss S., of Cincinnati, removing one ovary and tube which were badly diseased and bound down by adhesions. I used silver wire in this case as in case two, carrying it through the stump on one side and through the broad ligament on the other side, including the round ligament. Her uterus is still in position and she is restored to health. She had been an invalid for several years and unable to attend to her domestic and other duties.

CASE 4.—Mrs. J., of Indiana, was operated upon eighteen months ago. The urine and abdominal peritoneum were united by two buried silk sutures. Here uterus is still in position, and she is relieved of the symptoms for which the operation was done,

CASE 5.—Mrs. P., of Central Kentucky, was operated upon eight months ago. She was an invalid for many years. Her ovaries were cirrhotic, and were removed. Her uterus was sutured to the abdominal wall by passing a silk worm gut-suture through the stumps on each side. I saw her two months ago, and the uterus was still in position. From a very thin, nervous little woman she has grown to be quite fleshy and is restored to health.

CASE 6.—Mrs. L., of Louisville, was operated upon seven months ago. The uterus was sutured to the abdominal peritoneum with a buried kangaroo tendon. I saw her last week and her uterus is antiflexed and adherent. She was very much improved and says the operation has cured her. The ovaries and tubes were in a healthy condition and were not removed.

CASE 7.—Mrs. B., of Southern Kentucky. Ovaries and tubes healthy and were not removed. Uterus was held in front by silking worm gut sutures carried under the peritoneum of hhe uterus and brought out through the abdominal wall and fastened as in the first case. The sutures were not removed for two weeks. I did not scarify the uterus, and when the sutures were removed, I found that the uterus had returned to its abnormal position.

In some of these cases the sutures were removed within seven days, and the uterus is still adherent. Where the buried sutures were used, of course they were encysted or absorbed. In no case did I leave the sutures as long as fourteen days except in the last one, which is the only one of the seven cases in which the uterus did not remain adherent. In future I will always sacrify the uterus and I will either use the same method followed in cases one and seven, or use the buried silk, kangaroo or catgut suture. I have operated by other methods which I will report at another time.

Polk, Wylie, Dudley, and other operators, have treated retro-placed uteri by laparotomy and shortening the round ligaments before they leave the abdominal cavity.

# THE LIBRARY TABLE.

## BOOK REVIEWS.

*A Clinical Text-Book on Medical Diagnosis.* For Physicians and Students. Based on the Most Recent Methods of Examination By Oswald Vierordt, M. D. Authorized Translation, with Additions. By Francis H. Stuart, A. M., M. D. Third Revised Edition. 8vo. pp. 700. With One Hundred and Seventy-eight Illustrations, many of which are in colors. Philadelphia: W. B. Saunders, 1894. Price, Cloth, $4.00; Sheep, $5.00; Half-Russia, $5.50. Sold by subscription only.

This is the third edition of the English translation from the German of the well known work on medical diagnosis, by Prof. Vierordt, of the University of Leipsic.

That it has reached its third edition since 1891, together with the fact that it has been further translated into Italian and Russian, evidences its appreciation by the profession at large.

Taking the book as a whole, it is a master-piece and ranks probably next to Von Jaksch. Slight exceptions may be taken to some of the statements, but these can scarcely impair the value of the work as a unit. For instance, in describing the method for counting red corpuscles, he directs that the blood shall be diluted with a *three per cent.* solution of sodium chloride. This is an error not confined to Vierordts' diagnosis, but is noted in two or three other works including even Von Jaksch, and suggests a strong probability of copying one from the other, rather than the outcome of a clinical experience in blood work. A salt solution of this strength rapidly crenates the red blood corpuscles so that their enumeration is almost impossible. If salt solution is used at all it should be only six-tenths of one per cent. in strength—but in recommending this diluting fluid the author is not up to date, as it was clearly shown two years ago by Daland, and more recently corroborated by other observers, that by far the best fluid for diluting the blood is a two and one-half per cent. solution of potassium bichromate.

In counting blood corpuscles he says, use a magnifying power of fifty diameters. This must be an oversight as most authorities agree upon five-hundred diameters as the proper magnification.

He quotes from V. Jaksch, Osler, Dock, Shattuck, and others, as stating that a positive diagnosis of malaria can be made by the presence or absence of the plasmodium; which statement is misleading, for while the recognition of this parasite makes sure the diagnosis, our failure to find it in the blood does not positively exclude malaria.

In the section on "Examination of the Urinary Apparatus," we object to the statement that "exceptionally in health, there is found in the urine albumen, sugar, bile acids and fat." In describing the qualitative tests for albumen, Heller's, which is the most delicate test of all, is not even mentioned; and so, too, in speaking of sugar in the urine, Fehling's test which is very delicate, is not given as a *qualitative* test, but in recommending it as a *quantitative* method, he directs that Fehling's solution should be made by dissolving thirty-four thousand, six hundred and thirty-nine grammes of sulphate of copper in 500 c. c. of water; which is just one thousand times as strong as is correct. "Roberts' differential density method," the most practical quantitative method for the physician, is omitted.

There are, however, so many points of excellence in the work, that these few exceptions should not detract from its very great merit. Under the name of *Plegophonia* is described a method of percussion devised by Scherwald which gives the same information as vocal resonance, and is substituted in those cases where we do not wish the patient to speak aloud, as in hæmoptysis and peritonitis. It consists in ausculting the lungs while a second person, or the patient himself, percusses upon the trachea.

The microscopic examination of sputum is very fully and well illustrated. The chapter on examination of the digestive apparatus is thorough and gives the naked eye and microscopic appearances of abnormal and normal secretions in the feces and gastric contents; including also intestinal parasites which are illustrated with many plates.

The nervous system, occupying 135 pages, is examined in detail and introduces numerous cuts and diagrams.

Then follows an appendix describing Laryngoscopic and Ophthalmoscopic examinations of the throat and eye, and lastly a consideration of those bacteria which are concerned in the diagnosis of internal diseases, including those of suppuration, erysipelous, gonorrhœa, anthrax, malignant œdema, typhoid fever, tubefculosis, leprosy, cholera and the bacillus of Finkle-Prior, closely identical with the cholera germ.

The work is a valuable addition to any medical library and is attractively mounted.

---

*The Modern Climatic Treatment of Invalids with Pulmonary Consumption in Southern California.* By P. C. Remondino, M. D. The Physicians' Leisure Library, 1893. Geo. S. Davis, publisher, 25 cts.

This neat little book contains ten chapters, and is replete with valuable hints to invalids seeking climatic treatment. Not only is the climate described, but also the best method of travel and the cost of living is given. The book may be profitably read not only by consumptives about to migrate to California, but also by physicians who advise their patients to seek this climate.

---

*Clinical Gynecology; Handbook of Diseases Peculiar to Women.* By Thomas More Madden, M. D., F. R. C. S., Ed. Obstetric Physician and Gynecologist, Mater Misericordia Hospital, Dublin; formerly Examiner, Conjoint Board, Royal College of Surgeons and Apothecaries Hall, Ireland. Consulting Physician, Hospital for Sick Children; Ex-Master National Lying-in Hospital, etc., etc. With 259 illustrations and 545 pages. Published by J. B. Lippincott Co., Philadelphia, 1893.

The author has carefully embodied in this

volume many valuable and important facts, derived from his own experience of careful study and observation made at the bedside; an experience which covers almost a quarter of a century and during which he has been able to separate the "chaff from the wheat."

It certainly is within the memory of all when gynecology and obstetrics were taught by only one member of the college faculty, and diagnosis and treatment of pelvic diseases were still somewhat obscure. Since, however, the mists have been cleared by the united efforts of our French, English and German confreres, much has been written, said and done to place gynecology upon a more scientific basis, and a race began among the various eminent authorities, in which refinements of diagnosis, statistical tables of work done, as well as various methods of treatment took their respective places.

It is with a mingled feeling of pride and gratification that America accepts the kind recognition our author sees fit to bestow; when he says, "Should we, however need, as we all sometimes do, further light to guide our steps in the often dark and difficult paths of gynecology, it is not to France or Germany, but to America that we may best turn for our guidance; inasmuch as modern gynecology, unquestionably, owes its present development chiefly to the influence and teaching of the American and British schools of medicine."

"Thus, the marvellous achievements of modern intraperitoneal surgery now daily exemplified in both these great divisions of Anglo-Saxon gynecological practice, and in the latter more especially by the results obtained by Spencer Wells, Lawson Tait, Keith, Bantock, Doran, Thornton and countless other specialists in the operative treatment of ovarian and uterine diseases formerly considered beyond the possibility of radical remedy, are but the fruition of the skill and courage of an American surgeon. Had we no other reason than this for gratitude to our transatlantic brethren, it should be sufficient for us to recall the memory of that first ovariotomist, who in a remote Kentucky village, alone and under the most unfavorable circumstances, successfully accomplished what the leaders of surgery in the great centers of European science, from Ambrose Pare to Hunter and Lizars, had long previously dreamed of, but had not ventured to attempt, and so inscribed the name of Ephraim McDowell in imperishable characters on the annals of medicine and humanity."

In the chapter devoted to the Methods of Examination and the instruments necessary, he makes two important introductory remarks too often lost sight of; first, that of all gynecological instruments the skilled hand of the surgeon is the most important; second, that every examination should be preceded by the liberal use on the hands of hot water, nail brush and some antiseptic soap.

The author's consideration of the sound and its importance as an aid in making a diagnosis, is not borne out by most of the American gynecologists, although great care in its use is advised. The dangers in using it are so much greater than any possible knowledge gained regarding the exact position of the uterus, since by so doing it may unintentionally become the repositor, which the author expressly condemns, and thus relight a smouldering fire since the position of a freely movable uterus can, as a rule, be determined as well, if not better by the bimanual method.

The chapter devoted to Injuries of the Perineum and their treatment, contains valuable hints regarding its protection during the second stage of labor. He further advises that any laceration extending beyond the fourchette, which might prove a probable channel for sepsis if neglected, should be dealt with immediately after the expulsion of the placenta. After describing all known methods used for a secondary repair, he ends with the description of Duke's method which has been so productive of good results in the author's hands that he uses it almost exclusively.

Alexander's operative treatment for backward or downward displacements or any modifications thereof, are rejected by the author as impracticable, since they seldom deal with the cause, only relieving a symptom; the ligaments being elastic, will be likely therefore to stretch again.

We regret, however, that the method of treatment advocated by Schultze should find favor with him, though he recognizes its dangers, for after having quoted from the experiences of Macan, A. J. Smith and others, he says: "The dangers of Schultze's method are the risks of hemorrhage from the freshly separated surfaces, of which Smith relates an instance, or of subsequent peritonitis, which according to the same writer, will not occur if a thorough examination and proper selection in the cases so operated on be previously made."

Considerably space is devoted to the various and varied modern treatments of the diseased pelvic organs. The author has given this subject careful study, describing in detail all the new theories, supplementing many such with good wholesome advice and thereby checking the young enthusiast from accepting too readily those "fancy operations that may more safely be demonstrated on the lecturer's diagram board than in a patient's body;" and yet with all, we are somewhat surprised to find that he approves of aspirating per vaginam, a hydro- or pyo-salpinx, repeating this operation two or three times, if needed, placing such treatment under the head of conservatism. To our minds the walls of the hydro- or pyo-salpinx are left and perhaps other smaller pockets in the tortuous tube. The patient's health is far from being restored, since this residue often acts like dry tinder ready to ignite on the slightest provocation. In speaking of catheterization of the tubes he states that while he knows it can be done in abnormally dilated tubes, he believes it to be by no means devoid of danger. We cannot do other than heartily agree with the author, when he condemns "nor-

mal ovariotomy for epilepsy or insanity" as a species of malpractice, but we feel certain that should, however, patients afflicted in the above mentioned manner, and both history and local conditions (diseased appendages) be present, he would not hesitate to relieve her of, at least, *one source* of nerve irritation; and his experience has also, no doubt, shown that some of the operated cases by an inexperienced or careless hand, have suffered and thus served to intimidate often, not only another patient but also the operator.

In cases where removal of the appendages becomes necessary, he carefully describes the various steps of the operation.

There are several points on which American operators differ somewhat in the teachnique; for instance, drainage is generally used for a definite purpose, where pus has been present or when a large surface denuded of its peritoneum, and is decided upon before the wound is closed; the experience of most operators having been rather too unsatisfactory to rely on placing the drain secondarily; nor can we understand the necessity for cauterizing a stump after careful and secure ligation.

The after treatment also differs somewhat, since absolute rest of the stomach for at least twenty-four to forty-eight hours, has produced the best results, while the author advises chicken jelly four to five hours after operation, if wished for. The enema of Liq. opii sedativus in a wineglassful of iced champagne and Lithia water given after the operation, is also new to us.

The author takes up in turn the consideration of diseases of the uterus and their treatment, the complications sometimes following the puerperal period, ectopic gestation, etc., each being well worth careful perusal.

# CURRENT LITERATURE REVIEWED.

IN CHARGE OF ELLISTON J. MORRIS, M. D.

THE SAINT LOUIS MEDICAL AND SURGICAL JOURNAL

for January contains a paper by Dr. Edward Jackson, entitled

**A Study of the Relation of General Disease to the Development of Cataract.**

In brief, the points emphasized by the author are:

In general, senile change does not produce cataract, but predisposes to it.

The efficient determining causes of cataract are both ocular and general.

The general causes of cataract are not particular diseases, as diseases are usually described and classified, so much as physicial conditions liable to arise in the course of various diseases.

The nature, prevention, and removal of these general conditions that underlie the development of cataract offer promising fields for scientific study.

The professional supervision necessary for the making of such a study is demanded by the interests of the individual patient.

Speaking more scientifically, the study of a cataract case should include the careful testing of the vision at regular intervals.

The further examination of the eyes to determine in how far impairment of vision is due to cataract, and in how far it is due to other causes. The careful watching of the patient for other symptoms of impaired general health, especially for faults of circulation, digestion and assimilative metabolism.

Particularly at the first appearance of cataract, and at seasons of its rapid increase, would such a study of the case be of importance.

Dr. Homer M. Thomas discusses the subject of

**Pharyngo-Mycosis,**

meaning thereby a parasitic fungoid condition of the pharynx, manifesting itself in white patches of varying size resembling those seen in follicular tonsillitis, except that the mucous membrane about them preserves its normal hue. The tonsils, pharyngeal wall and base of the tongue are apt to be invaded. However numerous these small whitish projections may be, each spot is isolated, and they never form a continuous mass. After the tonsil, the glandular subtissue at the base of the tongue is most frequently affected; and the growth here may be extensive, the masses attaining the size of a pea. In some cases mycosis involves all parts of the pharynx. His experience in these cases leads him to believe that the galvano-cautery treatment is the most nearly a specific in the management of this disease of anything we have.

The other papers in this issue are: "Excision in the Treatment of Spina Bifida, with the Report of a Case," by Dr. John B. Roberts, which has already been published in THE MEDICAL AND SURGICAL REPORTER, for January 8, 1894, page 15, and a continuation of the translation, by Dr. Charles Everett Warren, of the "Prognostic Aphorism," by Dr. Gabriel Reignier.

THE AMERICAN JOURNAL OF THE MEDICAL SCIENCES

for February. Dr. Solomon Solis-Cohen contributes a paper on

**Vasomotor Ataxia—A Contribution to the Subject of Idiosyncrasies.**

The following is the author's summary of the paper:

1. By the term *vasomotor ataxia*, it it proposed to designate the condition of instability of the mechanism of circulation present in certain persons and characterized by abnormal readiness of disturbance with tardiness of restoration, of the equilibrium of the cardiovascular apparatus. The manifestations are most strikingly displayed by the heart and

by the peripheral vessels of the extremities, but analogy indicates the occurrence of similar phenomena in the vessels of the glands, and of the viscera, more especially those of the kidney, of the gastro-intestinal tract and of the brain. They may occur apparently spontaneously, but often there is a recognizable cause. Among the influences acting as excitants, are temperature, especially cold; toxic agents formed in the body, or introduced from without; visceral or internal reflex excitation and emotion. The stimulus may be applied centrally or peripherally, but in either case the resulting phenomena indicate a defect of central inhibition; the expression, probably, of functional or nutritional aberration in the great ganglia of the visceral nervous system, in the medullary centres, or in both. The morbid anatomy is uncertain, and the results of necropsies necessarily inconclusive.

2. Vasomotor ataxia may be acquired as a sequela of disease; in many cases it is congenital; in some cases inherited; the condition is not rarely present in several members of a family.

3. In some cases the phenomena are of paretic, in others of spasmodic character. Usually the two kinds of phenomena are displayed in varying degree in the same patient. Whether spasmodic or paretic the symptoms are suggestive of incoordination. They are always in some degree paroxysmal.

4. In exophthalmic goitre, especially, such cases as are produced by emotion or are markedly intermittent, is found the extreme type of the "relapsing" variety of vasomotor ataxia.

5. The form of Raynaud's disease, known as "local syncope" furnishes an extreme type of the "constrictive" variety; while "local asphyxia" exhibits phenomena of both abnormal relaxation and abnormal constriction of the vessels.

6. Between these two extremes are numberless gradations down to the slighest departure from normality; while even the extreme symptom-group represent merely exaggerations of phenomena that under certain conditions occur in normal individuals.

7. Dermographism is an essential feature of vasmotor ataxia, and in most cases factitious urticaria can readily be produced by cold or by pressure or by both; mottlings of the skin, certain peculiar markings of the nails, telangiectases and stigmata are common.

8. There is usually a hemorrhagic tendency, as shown by ecchymoses, petechiæ, epistaxis, hæmoptysis, hæmatemesis, hæmaturia, and retinal hemorrhage.

9. Even in the absence of hæmaturia, red blood-cells are often found in the urine; uric acid, urates, and oxalates are likewise common; the presence of albumin, tube-casts, and cylindroids is less common, and is usually intermittent. Glycosuria has been observed.

10. In many striking cases there has appeared to be morbid alteration of the thyroid gland.

11. The action of the heart is usually rapid, irregular, and easily disturbed; palpitation is common, and intermittent tachycardia has been noticed. Hæmic and functional murmurs are not uncommon.

12. Among others symptoms and morbid associations observed are anæmia, hysteria, drug idiosyncrasies, urticaria, local œdema. hyperidrosis, angina pectoris, and pseudo-angina, organic heart disease, pulmonary tuberculosis, asthma, hay-fever, vertigo, migraine and other forms of headache, transient hemiopia and other visual disturbances, persistent mydriasis, astigmatism, myopia, menstrual irregularities, intermittent polyuria rheumatism, rheumatoid arthritis, contractures of digits, chorea, epilepsy, neurasthenia, neurotic dyspepsia, gastralgia, enteralgia and membranous enteritis—most of which are doubtless fundamentally related, as effects of a common cause, or as secondary results.

13. In making the diagnosis of simple vasomotor ataxia, it is necessary to exclude primary organic disease. The occurence of such disease later does not invalidate the original diagnosis. The development of pulmonary tuberculosis in some cases is probably a sequence of vascular and atrophic disturbance in the lung. Cardiac hypertrophy and renal lesion may likewise be among the results of disordered circulation.

Dr. Edward P. Davis discusses

**The Toxæmia of Pregnancy: Its Diagnosis and Treatment.**

By the term *toxæmia of pregnancy* we understand a condition occurring in the pregnant woman in which toxic material is present in the body to excess. The mode of productions of the toxins, or poisonous waste, which threaten the pregnant women is not clearly understood though the author thinks it is in all probability due to bacteria. He urges most strongly the careful chemical and microscopical examination of the urine of all pregnant women. The treatment must be instituted with reference to promoting the action of five excretory organs—namely, the kidney, liver, intestine, skin and lungs. A milk diet is indicated in the author's opinion, but when nutrition suffers from the monotony and distastefulness of milk, we should not hesitate to give a more liberal diet. Fish and oysters, the white meat of fowls, fruits in abundance, and the more digestible sort of bread, fresh and nutritious, form a usually acceptable diet. Pure water must be taken but not in excess, as it is possible to seriously embarrass the kidneys by a sudden increase in the amount of fluid taken. Tea had better be omited, while the diuretic effect of coffee is sometimes of value. The occasional use of calomel and soda to promote the action of the liver and kidneys is of service; but should be followed by a purgative producing free and liquid stools. For this purpose salts of potassium should be avoided because of the irritant properties produced by potassium when introduced into the fluids of the body. Colocynth is a convenient and efficient drug for this purpose. The bath and pack are the only efficient remedies which experience suggests in promoting the excretory action of the skin. Where the hot bath is depressing,

the warm bath, accompanied by the ingestion of a small quantity of hot water, is of decided value. This may be well taken just before retiring, thus avoiding the danger of exposure to cold following the bath. Where a condition of moderate toxæmia exists, or continues for a long time, yielding to treatment with difficulty, great benefit will be found from gentle massage; this should include the limbs and back, avoiding the abdomen. It may well be given at night, followed by the bath, and often secures for the patient a refreshing sleep. The importance of fresh air in these cases cannot be overestimated.

As regards the cardinal principles of treatment, the author is opposed to the use of sedatives and narcotics; the patient's need is for elimination, and that must be secured as promptly as possible. The sedative effect of eliminative treatment is often remarkable. In the face of threatened eclampsia, our duty lies in the prompt emptying of the uterus. If an anæsthetic is required, the author favors chloroform. In his experience, it is a mistake to employ drugs which tend to depress the patient, and favor the occurrence of œdema; such as pilocarpine. When stimulation is needed, he has seen benefit from alcohol, digitalis, and in cases of eclampsia when labor had terminated and exhaustion threatened, in the hypodermic use of strychnia.

The remaining papers is this issue, are: The conclusion of a paper by Dr. W. W. Keen, entitled: "Four Cases of Brain Tumor, in Three of which operation was done—two operative recoveries—ultimate death in all;" "On Ascites connected with Nutmeg Liver," by Dr. John Syer Bristowe, and "A Contribution to our knowledge of Epidemic Cerebro-spinal Meningitis," by Dr. Simon Flexner and Dr. Lewellys F. Barker. This paper is illustrated with several woodcuts, and one colored plate showing sections of the spinal cord of a patient dead from the disease. The paper will be concluded in the next issue of the journal.

---

BABYHOOD

for February contains an article on "Cold Hands and Feet," by Wm. H. Flint, M. D. See page 246.

Dr. D. J. Milton Miller writes of

**The Evils of Indiscriminate Drug Giving in Infants and Children.**

While the writer does not insist that there shall be no domestic medication, he does protest against the reckless and haphazard use of drugs by the laity for all manner of supposed and real illnesses in children. He refers to the great abuse of laxative drugs, and states that castor oil, magnesia, and rhubarb are the most commonly used and abused drugs of this class. Among the alkalies, soda and soda mint are much used in the nursery for flatulence, nausea, and sick-headache, when the diet is really at fault.

The use of opiates, however, in the hands of the unintelligent is the most reprehensible. Children are peculiarly susceptible to this drug, and cases of death are on record, for which it is responsible. Administered in small doses continuously it brings about a low condition of the system, attended with constipation and failing appetite.

The emetics, epecac and hive syrup, are in common use in the nursery and are valuable in the hands of an experienced mother in cases of croup, but should not be used for more protracted ailments, as bronchitis and whooping cough. With reference to external medicines, the writer says blisters should not be used. Mustard plasters need caution in their use. No drops should be instilled into the ear for ear-ache or to cure a discharge. Sore eyes should be promptly seen by a physician.

Finally, the ailments of childhood have a tendency to self-cure, and the parents should avoid drug giving or give only simple remedies, lessen the diet and keep the child in bed or in the room; and if improvement does not speedily occur, a competent medical adviser should be sought.

Dr. Chas. G. Kerby contributes an article on

**Dentition.**

He says that the effect of this process on a child's organization is greatly overestimated, and bases some deductions on a thousand cases of this character. He divides the whole number into three groups: "The Breast Fed;" "The well-managed Artificially Fed:" "The badly Fed." In the majority of the first class the teeth were cut with practically no disturbance. In a very few there was irritability and restlessness, with some rise of temperature. The second class, or well-managed artificially fed, experienced no serious inconvenience. There was, however, more of a tendency to gastro-intestinal complications. To the third class, the badly fed, belong the great number of unfortunates who are given any and all sorts of food before the system requires or the digestive organs can bear such a diet. These are the infants who are said to "teeth hard." They have vomiting, diarrhœa, convulsions, fever, bronchitis, skin diseases, rhinitis, adenitis, otitis, stomatitis, coincident with teething; and the part which it plays in the matter is a very small one. The majority of the infants of the third class are rachitic and are far more liable to catarrhal troubles.

Irritability, restlessness, slight fever and gastro-intestinal derangement are the only symptoms that would be connected with dentition. The writer has never seen "tooth cough" or "tooth bronchitis," nor has he been able to trace a positive connection between dentition and skin diseases, tonsilitis, adenitis, stomatitis or convulsions. A fourth class, few in number, is the delicate offspring of healthy parents, such children often suffer from dentition.

A pernicious belief among the poorer classes is that a bronchitis need not be treated and that a diarrhœa is beneficial during the teething process. The giving of drugs for irritability and restlessness is seldom necessary. Gum-lancing is rarely required.

# PERISCOPE.

## THERAPEUTICS.

### Cocaine Wakefulness.

An interesting case of wakefulness by cocaine is reported by J. W. Stickler (*Medical Record*, January 13, 1894). The awakening effect of cocaine was not overcome by comparatively large doses of chloral and opium, as will be seen in the following instance: For the pain of toothache a patient took into his mouth nine grains of cocaine in solution, a small portion at a time, holding it till the accumulation of saliva became so abundant that he had to spit it ont. He began using the cocaine in this manner at 5 p. m., and did not cease till 10.22 p. m. the same evening. As it was then bed time he thought he would make sleep certain by taking twenty grains of chloral. Immediately after taking the latter drug he took into his mouth some more cocaine and went to bed. He "swashed" the cocaine solution about in his mouth awhile, then spat it out, turned on his side and tried to go to sleep. Sleep, however, did not come; on the contrary, he did not even become drowsy. Having lain awake till midnight, and not feeling sleepy at that hour, he took, as nearly as he could tell, about *one teaspoonful* of laudanum. He went to bed again and remained awake till three o'clock. Sleep lasted only two hours. Following this there was headache.

### Tuberculin Treatment in Egypt.

According to the *British American Journal*, Schiess and Kartulis give results of treatment with tuberculin in forty-eight tuberculous patients. They find that in the Egyptian climate the treatment is harmless if commenced with small doses, and even patients with anvanced phthisis may be treated by this method. They have compared their cases with others in which, though tuberculin was not used, the other conditions were the same. Their conclusions are in favor of the use of tuberculin; by its aid they say, commencing pulmonary tuberculosis gets well certainly, and in a few months, while advanced cases may also recover, although more slowly. Very severe cases, with vomicæ, hectic fever and night sweats, are unsuitable for this treatment. Scrofuloderma got well more quickly than lupus and tuberculin was also found useful in certain tuberculous affections of the joints and bones, in combination with surgical treatment. The Egyptian climate is, they think, especially suitable for the tuberculin treatment.

### The Treatment of Convulsive Attacks by Anæsthetics.

In the *Medical Record* of October 31, 1893, W. S. Magill described what he termed a "new and rapid method of anæsthesia," which consist principally in the administration of ethyl bromide first, this being continued by that of chloroform. In a later note (*Medical Record*, January 13, 1894) Magill invities attention to the utility of this combined process of anæsthesia for the abortive treatment of convulsive attacks in eclampsia, epilepsy and hysteria. The rapid action of the ethyl bromide-abolition of reflex action in thirty to sixty seconds, serves frequently to abort completely the convulsion; and in case of persistence of the tendency to convulsions (subintrans), the continuance of anæsthesia with chloroform prolongs the therapeutical action *ad lib*. Theoretically the stimulus of the salivary and sudoral glands (organs of elimination), exercised by the inhalation of ethyl bromide, should be particularly useful in eclampsia, and other convulsions of toxic origin.

## MEDICINE.

### Hot Water in Acute Alcoholism.

Burson (*North American Practitioner*, April, 1893) presents a series of eight cases of acute alcoholism treated by the administration of hot water in cupful doses, every hour, or more or less frequently. They were all males, and all gave a history of habitual alcoholism. One case was complicated with contusions; one with a fracture of the tibia; two with pneumonia; one with la grippe, and one with a traumatic hæmothorx. One had been given bromide of potass. (30 gr.) and choral (15 gr.) every hour for twenty-four hours, and one bromide (30 gr.) alone for five hours, with little sedative effect; and another had been given small amounts of whisky for three days without appreciable influence. All were confined to bed; some were restrained forcibly, and all received a cupful of hot milk every two hours as nourishment. The delirium averaged from two to three days after the treatment had been started, improvement beginning shortly after the beginning of the treatment. The author holds hot water to be decidedly indicated to relieve the inflammation of the gastric mucus membrane; to wash away the mucus covering it; to increase the inter-arterial blood pressure, and diminish the cardiac rate which have both been modified by the alcohol, as well as to quiet the nervous system and soothe the kidneys. It is also of great aid in removing the alcohol present, mixture being readily formed between warm water and alcohol.

### Typhoid Bacilli Conveyed Through the Air.

Formerly the spread of Typhoid fever through the air as a medium was regarded as a common occurrence, later this idea was no longer adhered to, as soon as it became known that a specific micro-organism was essential to the production of the disease, and that the agent could only be disseminated through the air in a dried condition. To-day

the question has been again brought forward. Various experiments and observations have been made with a view to ascertaining whether typhoid bacilli are capable of being transferred through the air. Still the re[illegible] thus far carried out lack two important [illegible] rst, the positive identification of the [illegible] bacilli; and Second, the duration of their vitality in a dried atmosphere.

The author in his experiments fulfilled these conditions scrupulously, and arrived at the conclusion that typhoid bacilli are conveyed to the air in a dried state from garbage and clothing, and that the bacilli retains their vitality for from several days to two weeks. —Prof. Uffelmann, (*Wien. Med. Presse.*)

### Flies and the Diffusion of Pathogenic Bacteria.

Dr. Simmonds' investigations on the transportation of cholera bacilli by flies, are of interest in that they give in the form of a definite experimental observation what has long been almost common knowledge. It is well known that flies that have access to tuberculous sputum take the tubercle bacilli into their intestines. If the flies are axamined histologically sometime after these bacilli may be demonstrated with the utmost readiness by the ordinary methods. It is probable, indeed almost proved, that other disease germs, such as the bacillus anthracis are carried from point to point by flies and now this has been superfically proven in the case of the cholrea vibrio. Dr. Simmonds placed a number of flies, which had from time to time settled on the viscera, etc. of a cholera case on which he was performing a port-mortem examination, in a flask large enough to allow of their free movement. As soon as they had been moving about long enough to insure their having got rid of most extraneous particles (about three-quarters of an hour) they were placed in a tube containing suitable nutrient gelatin, from which plate cultures were made. In a couple of days these plates were covered with colonies of the cholera bacillus, and the proof was complete. The influences to be drawn are obvious. The humble fly-paper vender is a far more useful and important personage than has yet been acknowledged.—*Brit. Med. Jour.*

## SURGERY.

### Transplantation of Free Cutaneous Flaps Containing Subcutaneous Adipose Tissue.

After combatting the opinion that all vital changes cease in a flap immediately the blood current ceases, he showed that circulatory currents continued for some time after removal of the flap, and furnished the first agglutinative material. It is evident that these current will be more lively, the more rich the flap is in blood vessels, and Diffenbach has shown that free flaps adhere more easily if one causes them to become congested by previously tapping and rubbing them. He operated with complete success on four patients, in the following manner:

After the application of Esmarch's bandage to the upper extremity, he struck for two or three minutes the upper and inner part of the arm with a rubber hammer. Then he cut a quadri-lateral flap of slightly larger dimensions than the loss of substance, detached it from the subjacent aponeurosis on three sides, leaving it attached by a pedicle turned towards the wrist. The ulcer was then vivid, and all bleeding stopped. He then removed Esmarch's bandage, and in a few minutes the flap became red and turgid. Its attachments were cut with strong scissors, and the flap was carefully applied to the loss of substance. He used gauze, or lint, as a dressing.—*Hirschberg, Frankfort.*

### Bremann (Halle). Treatment of Gunshot Wounds of the Abdomen.

A resume of his conclusions, based on observation of cases, is:

1. In all gunshot wounds of the abdomen, accompanied immediately with signs of a lesion of the stomach or intestine, or of a severe internal hemorrhage, laparotomy should be done at once.

2. Laparotomy is also urgently indicated in cases where the seat and the direction of the projectile admit the possibility of a wound in the stomach or intestine.

In support of this statement, he quotes MacCormic's statistics, that ninety-nine per cent. of patients not operated on will die.

### Korte. "Intestinal Obstruction by Billary Calculi."

The author has operated on three patients with the above condition, with two cures and one death. In all the cases the stones, although they were not very large, were so fixed that they could not be pushed forward or backward. Two were situated in the ileum, and one in the sigmoid flexure. The clinical symptoms were those of a very grave strangulation.

Medical treatment produced no good result. The calculus was easily found, the intestine was opened by a longitudinal incision, the stone removed, and the wound sutured.

## OBSTETRICS.

### Chloroform in Labor.

Dr. Eldrige C. Price says: If the pains are very sharp, I generally give chloroform, but only to take off the sharp edge of the pain and not for one moment to produce insensibilty. I call for a tumbler that is wide at the top,or perfectly cylindrical if I can get it; if that cannot be obtained a mug. Take a fine sponge or an old hankerchief, or a small napkin or a piece of muslin rag, that will fill the glass nearly half full, pour about a half teaspoonful of chloroform on the cloth and as soon as the pain comes on hold the glass inverted about half an inch

from the patient's nose. As soon as the pain passes off invert the tumbler on a marble top stand, or on a dinner plate, which prevents the evaporation of the chloroform but retains the vapor,so that it will smell stronger when you take it up again than when you put it down. As soon as the pain returns again use the chloroform as before. Add more chloroform when necessary. If I wish to produce insensibility I put an extra quantity of chloroform on the glass and let the patient inhale without interruption until unconscious. Then and only during the pain the patient does not become unconscious, but can scarcely get done thanking you for the relief.

I have never known the least unpleasant symptoms to occur from giving chloroform in this manner; but if profound insensibility is induced it is very apt to arrest the pains for from half an hour to an hour.—*New York Medical Times.*

## ARMY AND NAVY.

U. S. ARMY FROM JANUARY 21., 1894, TO FEBRUARY 10, 1894.

Colonel Joseph R. Smith, and Colonel Bernard J. D. Irwin, Assistant Surgeons General, U. S. Army, are detialed to represent the Medical Congress, to be held at Rome, Italy, March 29–April 5, 1894, and will proceed to the place designated atthe proper time.

Lieut. Colonel Francis L. Town, Deputy Surgeon General, U. S. Army, is relieved from duty at Fort Porter, New York to take effect on the expiration of his present sick leave of absence, and will report in person to the commanding General, Dept. of the Missouri for temporary duty in the office of the Medical Director of that Department.

Frst Lieutenant Euclid B. Frick, assistant surgeon, United States army, is relieved from duty at Fort Keogh, Montana, and ordered to Fort Townsend, Wathington, for duty at that post, relieving Captain Robert R. Ball, assistant surgeon. Captain Ball on being relieved by Lieutenant Frick, will report in person to the commanding officer, Fort Monroe, Va., for temporary duty. First Lieutenant Madison M. Brewer, Assistant Surgeon, will, upon the arrival of Captain Ball, be relieved from temporary duty at Fort Monroe, Va., and will return to his proper station, Fort Riley, Kansas.

Leave of absence for one month is granted Captin Reuben L. Robertson, Assistant Sureon U. S. Army, with permission to apply for an extension of one month.

The following named officers of the Medical Dept. are relieved from duty in this city to take effect upon the completion of the present course of instruction at the Army Medical School and are assigned to duty at the stations hereinafter designated:

1st Lieut. William W. Quinton, Asst. Surgeon, Fort Riley, Kansas; 1st Lieut. Thomas S. Bratton Asst. Surgeon Fort Niobrara, Nebraska; 1st Lieut. Deane C. Howard, Asst. Surgeon, Fort Buford, North Dakota; 1st Lieut Alexander S. Porter Asst. Surgeon, Fort Keogh, Montana; 1st Lieut. William H. Wilson, Asst. Surgeon, Fort Leavenworth, Kansas.

Leave of absence for two months, with permission to go beyond sea, is granted [illegible] Robert M [illegible]ford, January 18, 1894, U. S. A.

1st Lieutenant William Brooke, Asst. Surgeon, is relieved from duty at Fort Leavenworth, Kansas, to take effect upon the arrival of 1st Lieut. Wm. H. Wilson, Asst Surg. at that post, and ordered to Camp Pitot Butte, Wyoming, for duty.

## NEWS AND MISCELLANY.

A board of medical officers will meet, Monday, April 16, 1894, in Washington, D. C, for the purpose of examining candiates for appointment to the grade of Assistant Surgeon, in the Marine Hospital Service.

For further information address,

THE SUPERVISING SURGEON GENERAL,
U. S. Marine Hospital Service,
Washington, D.C.

### Smallpox.

There is not much change in the smallpox situation. In this State there are nine points where the disease exists, five of them in Berks County, and at nearly all of them under complete control. The case found at Williamsport on January 26th is the first new infected locality reported in three weeks. This city has, so far, escaped and the outlook in the State is hopeful. New cases are daily found at Chicago and New York, and the disease is slowly increasing in both cities. A case was reported at St. Louis, and one at Cotton Hill, Ill., the origin of both being traced to Chicago. On January 22d two cases were removed from the old Homeopathic Hospital on Ward's Island, and three days later one was taken from the Insane Asylum on Ward's Island. A short time ago there was a case found in one of the public schools of Boston, and on January 27th three cases were discovered in the Cook County Hospital, Chicago. The existence of the disease has also been reported at several places in Virginia near the Tennessee line.

### Higher Requirements for Entrance to Medical Colleges.

The Illinois State Board of Health amended the schedule of requirements for admission to medical colleges by taking out of the hands of the colleges the examination in the elementary branches of education, and requiring either a certificate or diploma from a literary and scientific college or high school or, at least, a second grade teacher's certificate. A curriculum of studies for schools of midwifery was also adopted. A committee was appointed to draft an outline of sanitary work throughout the State, and the secretary was ordered to issue a "preventive disease" circular on tuberculosis.

# ORIGINAL ARTICLES.

## SOME GENERAL CONSIDERATIONS OF PNEUMONIA.

LOUIS FIELDING HIGH, M. D., Woodburn, N. C.

Pneumonia stands preëminent among the diseases of which there has been much written and more said. It is not a disease that has been evolved from the march of civilization or sociological advancement. But who can deny that its prevelance has been increased by the modern ways of living, which, among some, are so much in discord with the laws of health as to produce a weak body incapable of resisting unsanitary influences?

Primeval man was exposed to the influences productive of the disease, like as we of to-day. Lurking everywhere, it has its victims, from the highest class and from the lowest; its subtle influence prevailing along the ranks of life from infancy to old age.

Notwithstanding the great advancement of medicine in the direction of an exact science, we have gotten but a little way from the views of past years in the treatment of this important disease. The great power of the microscope—that has been so faithful in its work and fruitful in results that by its aid surgery has eclipsed in advancement all the sciences during the last two decades—has not given to diligent investigators a sufficient acquaintance with the real cause of the disease to the extent of formulating a specific treatment nor the production of immunity. It it said that immunity to the disease has been produced, but that statement is not entirely free from doubt, though there is truth enough in it to lead us to hope its realization.

In reviewing the subject, it is striking to note the difference of opinion that exists in regard to the treatment of this disease. The want of harmony on this point is but a call for more definite information relating to its cause, pathology and treatment. Many theories have been advanced by earnest and observant workers, each hoping to give a better understanding or a more accurate comprehension of the cause or some feature of the disease bearing ultimately upon its mortality rate. But, as yet, we are in a state of uncertainty and doubt.

The old idea that pneumonia is caused by cold and exposure to meteiorlogical influences, now rests upon a questionable basis. The discovery of the bacillus of pneumonia by Fränkel and Pasteur gave encouragement and hope for a new order of means in dealing with the disease. But the fulness of that hope has not yet been realized. The evidences of its germic origin are still lacking in positive proof in all cases. Yet, while the exact part taken by the pneumococcus in the pathological process is not at present well understood, its constancy in pneumonic sputum as well as the success of inoculation experiments, is sufficient reason for the anticipation of a future mode of treatment that will have to do with the *disease* and not the *patient*. When once we are sure that the pneumococcus causes pneumonia and that we cannot have pneumonia without this germ, then will we leave the uncertain methods of treatment that have been battling the disease as far in the past as the history of medicine extends.

With the advancement of medicine and the establishment of more rational methods

of treatment of disease in general, we cannot claim high attainments in the treatment of pneumonia. The treatment of a half-century ago, though it was depressing and is sometimes called "murderous," gave results quite as favorable as the more modern stimulating and heart-tonic treatment. The mortality ranges from 3 to 35 per cent.; its average under all circumstances and methods of treatment is 20 per cent. If there is any improvement in the statistics since the days when all cases of pneumonia were bled and given depressing doses of tartar emetic, it must be due to the advancement made in the way of combating disease by nutritious and predigested aliment, rather than to medication. It may be true when many writers say they have not lost a case of the uncomplicated disease in a goodly number of years, but on trial it is found that their methods are not followed by the success claimed for them. Our test of another's treatment may in some point be faulty, still it may perhaps be well to look with some degree of skepticism upon statistics that give a death rate of ½ to 1 per cent. There is probably an error somewhere. The many and conflicting modes of treatment means at least one thing, and may be more, i. e., they are all inadequate of cure and prevention. The truth of the foregoing statement is the strongest presumption of its absolute microbic origin; it negatively demonstrates the presence of a germ or its product.

My experience in the treatment of pneumonia has not been of long duration. But it has been to that extent where I have seen some die in spite of treatment, and others recover without it. The natural tendency of the disease being to recovery much of the credit given to medicine really belongs to the natural resistance of the patient, or the mild nature of the attack. When we see eminent authorities endorsing special drugs, or lines of treatment diametrically opposed to each other, it must be that they, by a nice balancing of judgment, get in their work at one very particular turn of the disease. Truly, there are periods of the disease, in some cases, when cardiac sedatives, tonics or stimulants are the rational mode of treatment, but nothing could be more absurd than to give a patient some one, or all of these, for the very simple reason that they have been used in pneumonia. In some cases depressants may lessen the heart's action, and by slowing the circulation increase its nutritive functions and to a limited extent, strengthen the resistance of the tissues being acted upon by the infecting agent. Drugs that have a tonic effect on the heart and raise arterial tension, may, by contracting the arterial walls, lessen the migration of leucocytes and inflammatory exudation. Diffusible stimulants support the powers of life under the burden of depression. But all these means simply modify particular conditions, and leave the primary course, whatever its nature may be, uninfluenced and operative.

Venesection is being warmly advocated by men noted for their professional skill and experience. Preëminent among them is Dr. Hiram Corson, of Plymouth Meeting, Pa., a man of sixty-five years' experience. I think he bleeds in nearly every case and with very favorable results. Dr. William Pepper recently said (MED. AND SURG. REPORTER): "With continued caution, but, on the whole with increasing confidence, I find myself resorting to blood-letting." As a result of a careful review of venesection, I believe it has a place in the treatment of pneumonia that cannot, in the present state of enlightenment upon that disease, be filled by any other measure at our command. It can be beneficial by its effects on and through the circulation, lessening the volume of blood and so disgorging the right heart. It is self-evident that the engorgement and damming back of the blood upon the heart through the pulmonary circulation, is in direct ratio to the extent of obstruction and area of consolidation. As a result of such changes there is imperfect interchange of gases in the lungs, with a deficiency of oxygen and a harmful amount of carbon dioxide in the blood, all of which tends to increased heart-action and denutrition of the tissues. Though the heart's action is increased the circulation is sluggish, as is manifested by the cyanosis; the slowly moving blood favors the formation of heart-clot, adding to the dangers of pneumonic blood to coagulate or deposit fibrin in the heart or on the leaflets of its valves, a not infrequent occurrence. So we see the possible good that may follow the abstraction of blood in selected cases. In my humble opinion the time to bleed

is at the beginning of consolidation, for thereafter it is that the strain is put upon the heart; then cardiac engorgement begins and it is not yet enfeebled by overwork, and possibly before its endothelial lining is effected, which, as pointed out by Prof. Adolf Lesser, of Breslau, is not an unfrequent companion of pneumonia.

Theoretically, the urgency for bleeding is as the amount of consolidation; but a full and accurate comprehension of the condition present is necessary, if we would use this means for humanity's good.

## MEDICINE FOR A QUARTER OF A CENTURY.*

P. J. FARNSWORTH, A. M., M. D., CLINTON, IOWA.

An eminent physician and teacher of old New York, twenty-five years ago, said to his class, that "after all he needed but five medicines to cope with any ordinary disease." As it was my good fortune to have been a student under the teachings of that distinguished professor —his patients were multitudes and his success phenomenal—I have endeavored to go back in memory to the five noted medicines and something of his account of them.

It will be a surprise to our modern practitioners of polypharmacy, when they are named—Mercury, Opium, Quinine, Antimony and Iron. At that time these were a host of remedies. We have added largely to the list since, a flood of them, whose virtues are proclaimed by the myried press, and whose potencies are vouched for by the multitude of the profession. It may be well for us to consider what advantage we have gained, and what advance we have made over the old doctor.

We still retain Mercury. We have come to a new understanding of its action, but for its use we have reached few conclusions that the old doctors had not learned from their experience.

The old professor was chary of its use, but the practice of the older generation, who had used it as a panacea, heroicly, and on every occasion, was hard to escape from. Doctors, as a class, are conservative, and only by slow degrees change from the fashion of their fathers.

Thirty years ago it had been demonstrated that mercury did not necessarily affect the liver and that the continued and indiscriminate use was productive of the greatest injury, yet to this day there are those who cling to it as a sheet-anchor.

Its discovered power over germs has given a new impetus to its application, and made it something of the fashion now.

It was called an *alterative*—a term of vague meaning; it implied a changing of the secretions and a renovating of the tissue in some unknown manner; certain diseases were influenced beneficially, therefore, every one must be dominated by it. As we understand it now, it destroys germs and also all living tissue. At present, few of us own to much use of the drug, but none of us would have it stricken from our supply table. It is yet indispensable in syphilis and some kindred diseases, and in many places as a germ destroyer. We do not use calomel as a cathartic, or a sedative, or a placebo, as they formerly did. We have a wholesome fear of its destructive effect. Other remedies in most instances take its place.

For Opium we have no substitute. The old professor had mastered its use and his greatest triumph was from its application. He quoted with appreciation the words of Sydenham: "Without opium the healing art would cease to exist and by its help a skillful physician is enabled to perform cures that seem almost miraculous." It is one of the oldest of remedies. The ancient Egyptians used it and gave it name and all the generations since have taken it to ease their pains and soothe their distresses; it is a reliever of pain of every kind. It does more—in all our list of medicines it is the most curative. Not a temporary relief as many suppose but a positive cure for a large number of diseases. Many lose sight of this; it must be used with knowledge and judgement. We can account for the action of mercury in its power over living cells, but of opium we only know of its efficacy by observing its action where taken into the system. It relieves the most intense pain in whatever part without deranging or benumbing

* Read before the Clinton County Medical Society, 1893,

the rest of the body. After performing its office it is eliminated and leaves no trace behind. Other drugs stupify the brain, thus rendering the body insensible; opium besides quieting the throbbing nerve renders the brain more active. A concretion from the gall bladder tries to push its way through the duct. It is grasped spasmodically, putting the whole body into the most excruciating agony, agony so intense as to sometimes stop the whole vital machine. A few particles of a salt of opium introduced into the circulation, in a few seconds tranquilizes the pain as if by magic; the torment is over, the resisting duct relaxes, the obstruction passes and the current of life resumes its course as if nothing had happened.

The bowels have become irritable from poison or injury, inflammation has extended to the peritoneal covering, fever runs high, pain is intolerable. In earlier times death was almost certain, recovery was the exception. Blood letting, blisters, drastic purgatives with the indispensible calomel, were the remedies. Purgatives were of no avail. Mercury was no alterative.

The young doctor observed that relief and recovery sometimes followed the use of calomel and opium; he conjectured that it was the opium and proceeded to verify his conjecture. Some desperate cases were placed at his disposal and with careful assistants he pushed his remedy to its fullest limit. He held his patient under its influence until the disease subsided. He achieved a triumph in medicine that gave him a world-wide reputation and a desperate disease was mastered.

Not only in this form of inflammation, but in many others was its efficiency determined. It still retains its place in peritonitis; not even modern surgery has displaced it. It holds pain in abeyance, while the circulation resumes its course and the natural forces come back to their accustomed channels. It acts in lower degree when it quiets the minor frets of the body and leaves the mind free; pushed further, and it brings happy dreams. It is a seductive drug and becomes a vice that never releases its victim; yet, it may not shorten life or destroy the intellect of its votaries.

I need not give a dissertation on the use of opium. There are numerous and excellent ones, but they are not studied by the many, who failing to apply the remedy skillfully, reject it or speak ill of it. It passes for a temporizer, a delusion, a transient refuge while other remedies take effect, a cover for ignorance. It may be all of these in the hands of a bungler. In the hands of a master it is neither; it is the curative drug over all in the materia medica. I am ready to endorse Sydenham's eulogy of it: "Without it the healing art would cease to exist." The physician who does not master its use is not a skillful one, or a master of his profession.

Of Antimony much can be said, though my younger brethren have almost lost sight of it. The elder physicians depended on it for many purposes as their most reliable remedy. They ascribed great power to it over inflammation, and "over the formation and exudation of lymph," the significance of which we have almost forgotten. It is a slow but certain emetic, relaxing the whole system, reducing the heart's action and checking fever. Older people can remember when the glass with sixteen spoonfuls of water, each representing the sixteenth of a grain of "tartar emetic," was the invariable medicine prescribed for fevers, colds or any other disease, and the nausea and sweat that resulted. In pneumonia it followed after venesection. When that went out of use it still held its place, and now in many respects is preferable to aconite, veratrum or any of that class for the disease. In looking over Prof. Wood's Therapeutics, published in 1856, we find thirty pages devoted to Antimony. Used "to reduce arterial excitement, to promote absorption of effused fluids, to subdue inflammation and inflammatory states, in *bronchitis*, *pneumonia*, *peritonitis*, *hepatitis*, *nephritis* and the earlier stages of *rheumatism*, in *hysteria*, *cerebral excitement and delirium tremens*." When a dislocation of the thigh required the rack and the pulleys, relaxation of all the muscles was produced by a full dose of Ant.-Potas.-Tart. It is an older and undoubtedly as efficient a remedy for alcoholism as the Keeley cure. We are now using many substitutes for it with indifferent success. Without doubt, the next generation will rediscover its virtues, as many had done before Basil Valentine brought it into notice in the fifteenth century. Probably his competitors named it *antimony* or *antimonk*, from the destruction they averred it wrought among his brethren.

Quinine, or the cinchona salts that it

stands for, found its place when first introduced, and has maintained its ground to the present without displacement. It is the antidote for malaria, or that germ or poison that produces the specific fever called intermittent. It brought relief to what was considered an incurable disease of very wide prevalence. It rendered life endurable in many lands and made many countries habitable that before were dangerous to approach.

Boerhaave and his contemporaries of the lowlands, retired to the mountains at certain seasons to enjoy or endure their annual 'ague,' not to escape it, for it was in the system for all time ready to break out on any occasion. Now this is obviated; we stop the disease and relieve the system of it in any locality. Its range of action is limited; it is specific in the one disease and its complications. We have attempted to enlarge its scope; only casual observation will convince us that we have not succeeded.

In malarial lands the poison infiltrates the system and is ready to assert itself whenever fatigue or disease enfeebles or lowers vitality. Quinine removes the malarial factor and other remedies must be used for the other disorders. It is doubtful if it is beneficial as a bitter tonic, as it arrests digestion. Its beneficence is shown in the western country where ounces and pounds are used with no discrimination, a mere placebo; because necessary in some cases it is given in all, because it is at hand. No harmful results follow this extravagant use. It seldom leaves any trace after it. No substitute for it has yet been found. Its properties were only partially known to the old professor, who could not be reconciled to the heroic doses his western brethren were prescribing. It was a puzzle when a western student told him he had cured the intractable diarrhœa of the servant girl at his boarding-house by repeated five-grain doses of quinine. In non-malarial countries quinine is of little value.

Iron is one of the oldest remedies on record for its tonic or restorative effect. We know of its essential place in the corpuscles of the blood. Thirty years ago a wave or craze had set in in its favor which has in a measure subsided. It holds its place still, but the system sometimes fails to receive it and we substitute other tonics in its place. There must be, however, the due amount of iron in the blood, and when deficient we must resort to it in some of its forms as a restorative.

The Professor did not say that he confined himself to these five remedies in his practice, but that he might. He belonged to the incoming new school of practitioners that discarded the heroic practice of the old, and were denominated 'nihilist,' while at this time we would call this newer practice extravagant. "If I was very ill," said Dr. Squibb, of Brooklyn, to me about that period, "I would send for some of those big doctors of New York to diagnose my case and then call in some country practitioner to give me medicine." He probably thinks differently now.

The practice of medicine has made an immense stride in a quarter of a century. Many valuable medicines have been added to our list, but the greatest gain has been in the way of preventive remedies and measures. The list of medicines used by any of us now is very brief, ten or twelve will cover it. Not that we are not posted as to the others, but of all of the hundreds added, only three or four are of specific value. The rest are only variations of the old effects or shaded ones. We should not fail in our knowledge of them, but with all our knowledge we are limited to every small number of modifications of vital forces that are salutary. With skill a few remedies will produce all of them, the five named or even less. Water may be so manipulated as to accomplish all, or electricity, or the movement cure; they may be most serviceable in some cases, but in most they are cumbersome and only illustrate the ingenuity of the operator. Our progress in science has restricted rather than increased our use of drugs, the greater number are only auxiliaries or placebœs of not much value except for the period when they are in fashion. There are enthusiasts who are ever seeking novelties; they have yet a hope of finding the elixir of life and occasionally bring us something useful—in a generation some notably ones, only a few.

I have been a teacher and in active practice for the last twenty-five years, and as a close student of medicine endeavored to keep myself in touch with all its literature. I avail myself of all I deem of value of the latest arrivals, yet with all I am ready to endorse the saying of my old teacher, with five remedies I will combat all the diseases that arise in ordinary practice.

# COMMUNICATIONS.

## THE FIRST AMERICAN SYMPHYSEOTOMY.*

ROBERT P. HARRIS, M. D., PHILADELPHIA.

Until late in October last we were under the impression that the first symphyseotomy on this side of the Atlantic was performed by Professor Charles Jewett, of Brooklyn, on September 30, 1892, but it was then discovered that the credit belonged to Dr. William Thomas Coggin, now of Athens, Georgia, who operated in Freedman, Northeast Alabama, on March 12, 1892, more than six months before, with entire success; his residence at that time being in Keener, in the same mining region. Learning of Dr. Coggin's case at the time indicated, I opened a correspondence with him at once; have had ten letters from him since November 1, 1893; have secured a report of his operation for the *American Journal of Obstetrics*, for which it is now in press; and am here prepared to do him credit for the initial operation in this hemisphere. I should feel inclined to censure him for withholding his case from the profession for so long a period, but for the fact, shown in his first letter to me (November 2, 1893), that he was under an impression that as many as five operations had antedated his in this country. Had he known, as he does now, that he was the pioneer operator, we should, no doubt, have had an early report, and he would have been of influence in introducing the scheme to the favorable acceptance of American obstetricians.

The record of Dr. Coggin's case shows that Drs. Pinard and Varnier, of Paris, had nothing whatever to do with inducing him to perform the operation, thirty-six days after the initial trial of the former, as he had not heard of Pinard's case, or of their advocacy of the method. He was in Heidelberg in 1890, where he heard, from an Italian physician, an account of the remarkable successes under the operation in Naples, and received one of Professor Morisani's papers on the subject. He then decided to prefer symphyseotomy to craniotomy, whenever a case should come under his care in which one or the other should be presented as the alternative; and it was thus that he became the second to perform the operation after its exit from Italy. Had he been in a large city, he might have met with a proper subject much sooner, and have antedated Professor Pinard in his work, as he had in his acceptance of the applicability of the method. Dr. Coggin was a graduate in medicine of eight years' standing when he went to Germany, and prepared by experience to value a plan of obstetrics that opened to him a way of avoiding the objectionable one of craniotomy.

It is well know that no one in Europe, except in Italy, performed a symphyseotomy from 1865 to 1892, although from 1886 to 1892 there was enough in the measure of success attained to warrant its introduction into other countries. A mortality of 5½ per cent., we should suppose, would have secured imitators at a much earlier period, but for the fact that the Italians made but little boast of their work, and appeared to be indifferent upon the question of breaking up the old and deep-seated prejudice against the operation. Although aseptic and antiseptic measures had effected a revolution in results, it was not until a long record of successful cases had been collectively reported that the opposition of a century was made to give way. Having been in correspondence with the active advocates of symphyseotomy since the year 1882, I can understand the effect of the revelation of results that was made to certain Parisian obstetrical writers and observers, in Naples and Paris, during the winter of 1891-92. By that time there was such an array of facts in favor of the operation that it was only requisite to make them known to excite attention; for up to January 1, 1892, there had been in the preceding seven years thirty-seven Italian operations, with two women and three children lost. These cases were in order Nos. 11 and 24; the first of which had been in labor ninety-six hours, and the second, several days; case 11 died of septicæmia, and case 24 of metro-peritonitis.

Dr. Coggin operated upon the wife of a miner, a tall and apparently well-made

* Read before the Philadelphia Obstetrical Society, January 4, 1894.

primipara, 23 years old, and five feet and seven inches high, who had been fifteen and a half hours in labor when he was called in. He tried to deliver by the forceps, but found the pelvis too much contracted to admit the passage of the instrument, being of the *justo minor* type, and computed to be one-third smaller than the average. He opened the symphysis after sixteen hours' labor; applied the forceps; and in delivering the fœtus, which proved to be a male of eleven and three-quarters pounds' weight, noted that the pubic bones became separated two and three-quarters inches. There was no injury produced by the extraction of the child, either to the sacro iliac synchondrosis or to the soft parts.

Under a proper restraining apparatus the pubes readily united; there was no lameness, and the boy did well, as his unusually large size now indicates. There have now been thirty-five operations in the United States, and this woman was among the earliest to be operated upon, and bore the heaviest child but one of the thirty-five, the highest in weight being one of twelve pounds. Of the children, twenty-four were males and eleven females, and the average weight of thirty-three of them was eight pounds. This average is the best possible indication that, in our country at least, the minimum conjugate should be fixed for fœtal safety at two and three-quarters inches, or seventy millimetres.

As promptness in action is a very important element of success in symphyseotomy, we are surprised that there have been only four women lost out of the thirty-five cases, when we consider the fact that short labors have been the exception. As we have secured a record in hours of the duration of labor in the thirty-five cases, we are enabled to present the following analysis: Labor induced in 2 cases; labor before operation, of 6 hours or less, 1; 7 to 12 hours, 5; 13 to 24 hours, 15; 25 to 36 hours, 2; 37 to 50 hours, 6; 51 to 62 hours, 1; 63 to 76 hours, 2; and 89 hours, 1. The four fatal cases were in labor respectively 16, 20, 35 and 72 hours. Of the last 19 cases 1 woman and 5 children were lost.

It is of interest to note the order and date of introduction of the operation into the several countries since its exit from Italy.

The record of the year 1892 has been carefully collected by Dr. Franz I Neugebauer, of Warsaw; Professor Charpentier, of Paris; Dr. Francesco Caruso, of Naples; and the writer, under a reciprocal arrangement, whereby both published and unpublished cases have been recorded, and we have found 81, with 10 deaths and 24 children lost; France had 37 operations, with 6 deaths; Germany 11, with 2 deaths; Austra 6, with 1 death; Italy 9 and the United States 8, with no deaths; Russia 4, with 1 death; and there was 1 each in Brazil, Ireland, Switzerland, Holland, Canada and India, with 1 death, in the Holland case. Under the first thirty-one operations of the year, there were three women lost. In the first six months of 1893, there were more operations than in the whole of 1892, and the record of the year will probably reach two hundred, or more than the Cæsarean and Porro-Cæsarean cases of the world together.

It is worthy of note that France had forty-three operations, and had tested antiseptic symphyseotomy during a year before England, the twelfth country to follow the teachings of Italy, and her first operation; and, although this was entirely successful, others do not appear inclined

to repeat it. Old obstetrical writers in England are afraid of the Cæsarean operation, and do not appear to realize how much its mortality has been reduced, are strongly wedded to craniotomy, and cannot overcome their educated prejudices against symphyseotomy, the result of a century of training. Her younger obstetricians may in time learn, as we are doing, the value of the opeartion, and give it a fair, honest trial; but the medical profession is very slow in England in making advances; much more so than in her provinces, Canada, India and Australia.

There is much of a fallaby in calculating the risks of symphyseotomy by an average of results, taking all the cases together, good and bad. France twenty-five, and six out of her second lost three women out of her first twenty-five, a change from 12 to 24 per cent. Experience should have secured better results; but experience is largely individual, and properly refers to a repetition of the same operation by the same surgeon, as is very well demonstrated by the tables of ovarian exsection. In symphyseotomy the object should be to deliver the woman of a living child, and to save the lives of both; and anything that comes short of this is to that degree a failure. Another object to be considered is the avoidance of injuries to the woman in the opening of her pubes and the forcible delivery of her child. Haste has in it more of an element of risk of injury in the delivery than wisely-considered delay has.

Each case must be considered by itself in making a prognosis; the woman may have been a long time in labor; she may have a minimum cojugate, a small vagina and a large fœtus; the child may be barely alive or possibly dead, and the woman in a state of much exhaustion. What we call *good* cases generally recover; some *bad* ones, and even *very bad* ones, may do this, but they are to be regarded as exceptional; *extremely* bad ones rarely belie the prognosis.

Symphyseotomy in to many cases belongs to the surgery of emergency, and has to be classified as such. Where the subject is under observation before labor, and the size of the pelvis is tested by pelvimetry, rather than by a trial under the forceps, she will almost always make a recovery, provided she is not injured by a hurried delivery and has not had a hemorrhage produced by incision or laceration.

There is also a fallacy in calcuating the proportion of fœtal deaths by the number lost in a hundred cases under all operators. Where the pelvis is a fraction too small for the passage of the fœtal head, and the woman is operated upon early, she and the child should be saved; but where the disproportion of size between head and pelvic calibre is very marked, there is danger that the child may be lost. Under the eighty-one operations of 1892, there were twenty-four children lost, as follows: Still-born, ten; delivered in a dying state, three; premature and lived three days, one; and died within three days after delivery, ten. An early delivery should have reduced the deaths one-half.

The question is often asked me in letters, what is the death-rate under symphyseotomy for the women and the children? We cannot estimate what should be the prospective risk under the operation, as we have already shown, for so much depends upon varying conditions which may be favorable or the reverse.

Recent experience has shown conclusively that some of the old objections to the operation have been removed under antiseptic surgery. Failure of the pubic symphysis to unite, and lameness produced thereby, are no longer tenable objections. Injuries to the sacro-iliac synchondroses are not recorded in connection with any recent sections in Europe or America, and lacerations of the soft parts, which should seldom occur, can be treated so as to restore them to their integrity and avoid septic infection. The symphyseotomy of to day is a much-more innocent operation than that of a century ago; and we see no objection to using it as a substitute for craniotomy when the case is in skilled hands.

As far as ascertained, there were twenty-seven symphyseotomies in the United States in 1893, and there have been forty operations in North and South America, with four women and nine children lost, a maternal mortality of ten-per-cent. There have been twelve operations in Philadelphia, or one-third of those in the United States, all performed by members of this society. The operation has been performed in ten States and by twenty-six opeartors. Twenty-eight of the cases were in our large cities.

# THE ETIOLOGY OF THE DISEASES PECULIAR TO WOMEN.*

T. GAILLARD THOMAS, M. D., NEW YORK.

Although morbid conditions may develop in connection with the genital system of the woman at any time of her existence intervening between "the cradle and the grave," it is beyond question true that there are in her life four great climacteric periods, in connection with which the great bulk of the diseased states to which she is liable develop; in which I should venture, at a rough estimate, to assume that nearly eight-tenths of all of these conditions take their rise. These climacterics may thus be presented at a glance:

1. Puberty, marked by progressive metamorphosis of the ovaries and resulting ovulation and menstruation.
2. Marriage.
3. Child-bearing.
4. The menopause, or change of life, marked by retrograde metamorphosis of the ovaries and resulting cessation of ovulation and menstruation.

*First climacteric.*—It is the ovaries which mark, by their rise to and fall from power, the beinning and the end of woman's functional career. Hippocrates, over two thousand years ago, enunciated the dictum, *propter uterum mulier est.* It was left for our own Peaslee to correct him by changing his formula to *propter ovarian mulier est*, which is the motto which he places at the opening page of his work upon ovarian diseases.

True it is that with ovarian advance and retrogression a simultaneous change occurs in the uterus, but no one will to-day dispute the fact that the first constitutes the cause and the second the result; that the change in the first is the phenomenon and that in the second the epiphenomenon.

From the birth of a female child to its thirteenth year the girl is being prepared by nature for meeting the first great climacteric of her life; and fortunate it is for her if surrounding circumstancee do not interfere with her development, or the ignorance or neglect of her guardians defeat the accomplishment of the result. During the first two-thirds of this time of preparation the uterus, ovaries and adnexæ of the child remain almost entirely dormant. Then, as she advances to the third period, they begin to undergo development, and toward the end of this period the development becomes accentuated, rapid, vigorous and perfect. Then the ovules break away from the Graaffian follolicles, the Fallopian tubes seize them, and pass them onward to the engorged and swoollen uterus, and the great issue which translates the child from girlhood to womanhood has been met.

If the changes preparatory to this event have been properly performed, all goes well; but if from any cause the growing uterus has been checked in its development, been made misshappen so as to resemble a gourd, or been developed fully for half its bulk and made atrophic in the other half; or if the ovaries at the time of call to duty are wholly or in part undeveloped and incapable of performing their functions; or, if the Fallopian tubes or vagina are constricted or impervious, a variety of so-called diseases show themselves, all of which are difficult of cure, and many of which are entirely incurable. If malformed ovaries exist the most agonizing ovarian dysmenorrhœa, amenorrhœa, or emansio mensium, with their sometimes coexisting hysteria, hystero-epilepsy, and even epilepsy, show themselves, and hold out to the poor woman the prospect of a life of invalidism, or at least a lengthy and discouraging course of treatment. Who, in this room does not recall many cases of this kind, which beginning with the very inception of menstural life, have proved most rebellious to currative treatment? If the Fallopian tubes have been strictured by want of development, atrophy, or constriction by out-lying lymph, the girl suffers from severe pain at menstruation, or later in life becomes an invalid on account of sterility or tubal pregnancy. If the vagina is constricted or impervious, retension of blood in it or in the uterus becomes an important factor for evil.

Suddenly, the occurrence of this climacteric, created solely by ovarian dictation, makes an imperious call upon organs

* Read before the New York County Medical Association, December 18, 1893.

hitherto insignificent, and finding them unequal to the demand, a long list of ailments develop themselves as a consequence. On the first day of a month, the girl had been remarked upon as a type of female health, vigor and beauty; on the fifteenth of that same month, the imperfect way in which she has grappled with the functions of her first climacteric have assured her physician that years of invalidism in probability lie before her.

By the patient's friends, even by her physician, if he be a short sighted and superficial observer, the trouble which has occurred is attributed to cold, to fatigue, to mental anxiety, or the like; but "the inexorable logic of events" is destined to belie this hope. If the chief system be dysmenorrhœa, the condition is carefully classified into "neuralgic, ovarian, congestive, or obstructive," and the physician very properly strives to overcome it by using the best efforts to meet a disability, which is commonly due to imperfect performance of those changes which mark the period styled "puberty." If the vagina be constricted or the cervical canal be imperious, they are distended and kept open; if the ovaries are at fault, general treatment by nerve and blood tonics, exercise and calisthenics and local treatment by pelvic massage, and electricity and galvanism, are appealed to, and after a variety of means have been tried in vain, and grave symptoms still exist, the process of ovulation is abolished, and the evil dependent upon it relieved by the humane scientific and entirely defensible operation of removal of the tubes and ovaries.

Fortunate is it that many evils entailed upon the woman by "puberty" are oftentimes susceptible of complete relief. There are, however, some which project their influence into her future life and show themselves after marriage in various ways. For example, a deformed uterus may be the cause of frequent abortions, which no resource of art is capable of preventing; constricted tubes may give rise to hæmatosalpinx and perimetritis the outcome of peri-salpingitis; while obstruction to the transit of the fructified ovum into the uterus commonly gives rise to ectopic gestation.

Surely it is no exaggeration to style this one of woman's great climacterics, one of the periods in her existence which is fraught with the profoundest import for her health, her usefulness and her happiness. If it be true, as I have said, that the period intervening between a girl's birth and her passage into womanhood is the time of preparation for this, her first great climacteric or critical period, much as to her fitness for meeting the issue will depend upon the proper physical development accomplished in this preparatory time, and all those who watch her career—physician, mother, and teacher—should join hands in sending her into the arena as thoroughly prepared as it is possible to make her for her new functions.

*Second Climacteric.*—The first climacteric being passed, the girl emergies from it a young woman, and enters into that period of her life which intervenes between puberty and marriage—speaking approximately, a period extending from the thirteenth to the twentieth year, covering about seven years of her existence. Although during this time falls, muscular efforts, exposure to cold, and pathological changes of tissue may, of course, produce disease, this is, to one who has successfully met the issue of puberty, usually a cycle of health and happiness. Then occurs a second climacteric, which sometimes proves a most baneful one to the healthy and robust woman who enters into it—marriage.

There are three morbid states which now frequently show themselves: First, the development of vaginismus, or spasm at the vaginal outlet; second, specific vaginitis, endometritis, and salpingitis, and third, the manifold evils resulting from the induction of abortion by women who resort to this fatal and criminal practice, not to protect their characters from disgrace, but merely to suit their social convenience, or from dread of the dangers of childbearing.

Of the first and third of these I shall say no more, as the management of the first is quite simple and generally understood; and as a mere mention of the third is all that I deem necessary. Of the second, I shall speak more fully and venture to quote upon it from an address given by me which has already appeared in print.

Until the last twenty years specific urethritis was regarded, in the male, as an affection of the most trivial import, as rapidly passing off, leaving few serious sequelæ, and offering itself as an excellent subject for jest and good-natured badinage.

About two decades ago Dr. Emil Noeggerath published a dissertation upon this affection, which will forever preserve his name in the list of those who have accomplished good for mankind, and give him claim to the title of benefactor of his race. This observer declared, first, that out of growing young men a very large proportion prior to marriage have specific urethritis; second, that this affection very generally causes urethral stricture, behind which a "latent" or low grade urethritis is for many years prolonged; third, that, even as late as a decade after the original disease had apparently passed away, the man may transmit it to a wife whom he takes to himself at that time; and fourth, that the disorder affects, under these circumstances, the ostium vaginæ and urethra, and thence passes up the vagina into the uterus, though the Fallopian tubes, where it creates specific catarrh, and by this disease produces oöphoritis and peritonitis, which becomes chronic, and often end in invalidism and sometimes even in death. For this essay Dr. Noeggerath was assailed by ridicule and by contradiction. The matter has now been weighed in the balance and admitted to its place among the valuable facts of medicine.

My estimate of specific urethritis as a factor in the diseases of women, and I take no peculiar or exaggerated views concerning the matter, will be vouched for by all progressive practitioners of gynecology to-day. Specific vaginitis, transmitted to virtuous women by men who are utterly ignorant of the fact that the sins of their youthful days are at this late period bringing them to judgment, is one the most frequent, most active, and most direful of all the causes of serious pelvic trouble in women—one which meets the gynecologist at every turn, and one which commonly proves incurable except by the dangerous procedure of celiotomy.

Think for a moment of the terrible position in which a high-minded, upright, and pure man finds himself placed without any very grave or unpardonable fault on his part. At the age of nineteen or twenty, while at college, excited by stimulants, urged on by the example of gay companions, and brought under the influence of that fatal trio lauded by the German poet —"Wein, Weib, und Gesang"—the poor lad unthinkingly crosses the Rubicon of virtue! That is all! On the morrow he may put up the prayer, "Oh, give me back yesterday!" But yesterday, with its deeds and its history, is as far beyond our reach as a century ago, and returns at no man's prayer!

Four or five years afterward this youth goes to the marriage-bed, suffering, unknowingly, from a low grade of very slight latent urethritis, the sorrowful memento of that fatal night, which has existed behind an old stricture, and a result is effected for the avoidance of which he would most gladly have given all his earthly possessions.

All this sounds like poetry, not prose; like romance, not cold reality. But there is not a physician in this room who does not know, and who will not at once admit, that every word that I have uttered is beyond all question true, and even free from exaggeration.

I mentioned, in speaking of the grave duties demanded by puberty, that one of the important functions of the physician in regard to the development of the girl during the thirteen years which precede it, is to instruct her and her guardians how to prepare her for the approaching issue. In language no less strong I would here insist upon the physician's duty to instruct men in all stations of life as to the importance of a "clean bill of health" in reference to gonorrhœa, both acute and chronic, before the marriage contract be entered upon.

Until a very late period the plan universally followed has been this: The man about to be married went to his physician, told him the history of a gonorrhœa, and asked if, now that all discharge appeared to have ceased, any danger would attend his consummating the tie. The physician would ask a few questions, examine the virile organ carefully as to discharge, and if the "outside of the platter" appeared clean, gave his consent to the union. The evil which has resulted from this superficial and perfunctory course has been as great as it has been wide-spread. To day the question of stricture, a slight, scarcely perceptible "latent gonorrhœa," with its characteristic "gonococcus," is looked into, and not until all trace of disease is eradicated is permission given for the union. A marital quarantine is as necessary to-day in social life as a national quarantine is for contagious diseases in general.

Few men, however eager for matrimony they may be, would run the great risks attendant upon precipitancy if they only knew of them clearly and positively. In no field of medicine is the old adge, "Prevention is better than cure," more important than in this one. If physicians would do their duty fully in the matter, how many unfortunate women now languishing from "pyo salpinx" would in the next generation be saved!

*Third Climacteric.*—Let us suppose that the girl has passed through puberty and become a wife, and that no evil has thus far befallen her in either of these stadia of her course through life. The probabilities are that within a year or two she will be called upon to face still another climacteric—that of utero gestation and childbearing.

The passage of the human fœtus through the short, mucous-lined canal which leads from the superior through the inferior strait of the pelvis is attended, even in labors apparently normal, by certain traumatisms which have a most disproportionate bearing upon the health of the woman who suffers from them. The reasons for this are not far to seek. Slit the cervix uteri or the perineum freely with a bistoury in a non-pregnant woman, and little, if any, serious injury would result. The parts would cicatrize and nature would prove herself abundantly able to deal with the trouble. But let a laceration of these parts be effected by the child's presenting part during labor, and a series of events takes place which casts its baleful shadow over the future life of the woman. This unquestionable fact is due to two circumstances which render the parturient woman peculiarly vulnerable to traumatism exerted upon the genital tract in any part of its extent. These circumstances are the following: 1. From the moment of fixation of the ovum upon the uterine wall until the end of gestation a rapid hypertrophy of all the sexual organs occurs. The only phenomenon in the physiology of the pregnant woman which is as wonderful as this is that retrograde process of involution which restores these parts to their normal state, so that at the end of eight weeks the immense uterus, the voluminous broad ligaments, the copious vagina, and the distensible perineum return to their lessened state of non-puerperality. 2. Wounds made in the genital tract of a non-puerperal woman are bathed during their repair by a bland mucus which is secreted by the glands of the cervical canal and by the vaginal membrane. Similar injuries inflicted upon the parts of a parturient woman are bathed by the lochial discharge, made up of ichorous material, holding in admixture flaking decidua vera, disintegrating placenta, and decomposing blood, which, even under favorable circumstances, sets up a sapræmia, and, under unfavorable ones, tends to the development of a dangerous septicæmia.

Such wounds are not prone to heal by nature's efforts, often assume bad features, and interfere greatly with that wonderful and subtle process of involution just alluded to. As a consequence an arrest of retrograde metamorphosis often affects vagina, uterus, uterine endometrium, and broad ligaments, and creates a marked disproportion in the normal relations of all the pelvic viscera at the same time that it weakens those supports which formerly sustained them. In this way we often see as direct and remote consequences of laceration of perineum and cervix uteri some or all of this long list of pathological results:

1. The vagina suffering from subinvolution and unsupported by the perineum, begins to undergo prolapse, its posterior and then its anterior wall pressing downward into the vulva.

2. Prolapse of one wall soon deflects a wall of the rectum and that of the other of the bladder, and misdirection of the forces of these viscera add their influence to increasing vaginal prolapse.

3. Traction by vagina, rectum, and bladder soon affect the uterus, and descent of this organ begins to show itself.

4. The uterus is the more prone to descend under traction because involution has been rendered imperfect in it, and its increase of weight and feeble support from subinvoluted broad and round ligaments render it helpless.

5. Menstruation now occurs, and a granula, almost fungoid, condition of the endometrium, existing in consequence of impaired involution, menorrhagia supervenes and adds its depreciation influence to the concatenation of morbid influences which are rendering the condition of the poor woman more and more wretched.

Could such a collection of untoward symptoms be possible from wounds inflicted by bistoury or scissors upon the perineum and cervix of a non-parturient woman? Not at all. Such results can be accounted for only by the interference of these traumatisms with the performance of an important physiological function, upon the fulfilment of which depends a return of every puerperal woman to the domain of health.

To sum up this part of my subject, there can be no doubt of the fact that a large proportion of the diseases peculiar to women are due to injuries inflicted upon the genital tract during labor, and that among them may be numbered, subinvolution of uterus, vagina, and perineum; fungoid endometritis; uterine catarrh; menorrhagia and metrorrhagia; any of the displacements of the uterus; prolapse of bladder, rectum, and vagina; cystitis; and secondary derangement of the blood and the nervous system, which react upon all the organs of the body.

To overcome these pathological results the obstetrician to-day repairs lacerations of cervix and perineum, lessens the volume of uterus and vagina, shortens the round ligaments, and scrapes away the entire lining membrane of the womb. When it becomes the accepted and universal practice to examine for these traumatisms after every labor, and to cure them by surgical means as soon as practicable after delivery, the diminution which will occur in the annual crop of sick women will wonderfully diminish.

Some years ago, in my clinic in the College of Physicians and Surgeons of this city, being desirous of impressing these facts upon the students, I requested them to notice how frequently each patient who appeared before them would refer the cause of her disease to one of the critical periods mentioned, and agreed that we would review the subject at the end of a month. The result served to fix the fact most clearly in their minds by the frequent, indeed almost constant, recurrence of the phrases, "I was well until my periods began;" or, "My disease showed itself soon after marriage;" or, "I have never been in good health since my last labor, or since a miscarriage at such a time." That there were exceptions to this I need not mention, but they only appeared to be sufficiently frequent to prove the rule.

*Fourth Climacteric.*—We come now to the consideration of the menopause, or change of life, which has been from time immemorial known as the technical "climacteric" of woman.

When the far reaching nervous influences exerted by ovulation and menstruation upon the system of the woman, which continue active for thirty-five years of her existence, are borne in mind, one is prepared to expect decided mental and physical manifestations when a sudden cessation of ovular activity occurs about the fiftieth year. And certainly at that time the nervous system of the woman does become especially liable to loss of balance, as demonstrated by hysterical and nervous manifestations, and even by a tendency to melancholia and other psychic derangements, while disorders of the menstrual flow become marked, decided, and troublesome, and serious tissue-changes in the pelvic viscera appear to be especially frequent. While all this is admitted it cannot be denied that too great stress has been laid upon this period of woman's life as a critical epoch, and that many pathological conditions occurring about this time have been credited to it which have had no connection with it at all.

The swing of the mental pendulum in reference to the matter must be carefully supervised as to both its extremes; the gynecologist being careful, on the one hand, to avoid an over-estimate of the importance of this epoch which leades to making it a shield for incapacity or ignorance; and on the other, being wary of an under-estimate, which may cause him to lose the great advantages which may result from a postponement of operative interference until its occurrence be allowed to exert its legitimate beneficial influence. Indeed I feel that I stand upon defensible ground when I assert that the chief significance of the menopause to the gynecologist exists in the fact that it constitutes a haven of rest for the woman from many ailments which are due to menstual disorders and to hypertrophy and hyperplasia of the uterus. It ordinarily puts an end to subinvolution and uterine hyperplasia, to menstrual irregularities, to metrorrhagia, and to uterine myomata. With such certainty can these results be counted upon that operations for such conditions may be held in reserve, in the hope that by this climateric the necessity for them may be avoided.

Some years ago, when the effects of galvanism in the cure of uterine myomata was upon the crest of the gynecological wave, a former pupil of mine, a man of great industry, enthusiasm, and honesty, requested me to read, prior to publication, a report of twelve or fourteen cases of uterine myoma in which small tumors had been completely cured, and large ones greatly benefited and checked in growth, by this, then new, therapeutic resource. It was not a report of his experience with the method, but one embodying his successful cases. Upon a careful analysis I found that all the cases of recovery and amelioration had occurred in women between forty-three and fifty-three years of age, and that each recovery was coincident with cessation of menstrual flow and other signs of the menopause. The pleasure of reading this honest and laborious account of faithful work was never enjoyed except by the writer and myself, for it did not appear in print!

At the time of the menopause, as atrophy of the cervix uteri and atresia of the cervical canal take place, retention of discharges from the endometrium sometimes occurs, constituting hydro-metra, hæmato-metra, pyo-metra, and when decomposition of the arrested fluids supervenes, the rare condition of physo-metra shows itself.

Two forms of senile vaginitis are apt also to develop themselves about this time —adhesive vaginitis, which closes the vaginal canal entirely, and hemorrhagic vaginitis, which I have on several occasions seen mistaken for carcinoma uteri, on account of its causing sanguineous flow in a woman who has for some time ceased menstruating. In this connection this diseased state is of importance, for the patient will always come to the physician in the greatest state of alarm. Fortunate is it that this alarm may be quieted by the promise of complete recovery.

Lastly, at this climacteric procidentia of the atrophic senile uterus is apt to occur from rapid absorption of adipose tissue, in the pelvis, which causes it to descend from want of support, and inflicts upon the woman a disability at the end of her career, and after she has borne triumphantly the burdens of life.

This completes the list of the most important of the pathological conditions which develop in connection with the menopause, the fourth climacteric of woman's life.

**The First State Hospital for Epileptics.**

Thanksgiving Day was observed with peculiar appropriateness in the little town of Gallipolis, in the southern part of Ohio, for the day marked the opening of the State Hospital for Epileptics, the first of its kind in this country.

---

Wounds of the Heart.—It was formerly believed that wounds of the heart were always fatal. Recent investigations, however, show that a fair proportion of these cases is amenable to cure. Dr. Lumniczer has reported five cases of wounds of the heart and pericardium, only one of which terminated fatally, and Dr. Peebles (Omaha Clinic) reports a case of bullet wound of the heart with recovery. Dr. Heine Marks (*Medical Fortnightly*) has treated two cases of stab wounds, in one of which recovery ensued in spite of the fact that examination with the finger revealed the presence of lesions of the diaphragm, pleura, pericardium and apex of the heart. The literature contains records of many similar cases.—*Int'l Jour. of Sur.*

The Brookyln Polytechnic Institute announces a new four-year's course in Practical Chemistry, under the direction of Professor P. T. Austen, Ph. D., F. C. S., of Rutgers College and Scientific School, New Brunswick, N. J. Professor Austen is especially known to our readers by his valuable work in water analysis and the philosophy of precipitate-filtration. He is a graduate of Berlin, as well as of the regular course in this country.

---

Kitasato, Koch's able Japanese pupil, who has gone back home on a snug allowance from his government of $45,000 to get started and $15,000 a year afterwards, is reported to be already treating consumption with remarkable success with tuberculin modified by himself.

---

Sugar and the Teeth.—The common experience of decay in teeth from too much candy is explained by a professor of physiology, who is an eminent dentist, on the ground that sugar prevents the proper assimilation of the lime salts, and thus interferes with the nutrition of the teeth and other bony tissues.—*Ex.*

# TRANSLATIONS.*

## TREATMENT OF ADVANCED CARDIAC DROPSY BY THEOBROMINE.

Germaine See at the August meeting of the *Académie de Médecine* (*Le Bull. Médical*, Aug. 2, 1893), offered an interesting review of the rôle played by theobromine in the treatment of cardiac disease. Theobromine is a dimethylxanthine obtained from chocolate; it is also the inferior homologue of caffein, which comes from tea, coffee, maté, and in small quantities from kola nut. Whilst caffein is soluble in sodium benzoate or salicylate, theobromine is absolutely insoluble in these salts. The so-called diuretin is by no means the equivalent of a salicylate of sodium and of theobromine. It is, in fact, nothing else than about 18 grams of theobromine dissolved in about 4 grams of caustic soda, to which is added 16 grams of salicylate of sodium. The presence of the caustic soda in the diuretin suffices to explain the harmful effects of this drug upon the stomach and upon the circulation. Moreover when one employs diuretin he administers double or three times the dose of theobromine.

As a diuretic theobromine is superior to digitalin, strophantin, caffein, milk, lactose and sugar. It acts upon cold-blooded animals more actively than caffein, but without producing the manifestations of excitement of the nervous centres, and without determining poisoning unless given in a dose five or six times stronger than that of caffein. Its diuretic power is established without adding a narcotic to the theobromine to destroy its vaso-motricity as is the case with caffein. It should be prescribed absolutely pure without an auxiliary. This, with a dose of 5 grams of theobromine, a diuretic effect three times more marked than that of caffein may be obtained. The diuresis lasts for twenty hours instead of but six hours as in the case of caffein. It commences in from about three to four hours and reaches its maximum in from one to two days of the theobromine treatment. The caffein diuresis is more prompt but without persistence. It is worth noting that in exciting the secretory system of the kidney, theobromine does not modify the previous condition of the urine; when albumin is present, it is not increased nor diminished in amount; when there is an excess of urea, it remains at the same point. The digestive organs are rarely affected by the drug. It may in large doses produce vomiting and nausea, but all that is necessary then is to subdivide the dose. The nervous system remains intact; there does not follow nervous excitement, insomnia, agitation, somnolence, whatever may be the dose of theobromine administered. As the dropsy disappears under the use of theobromine the respirations become more easy and regular; the dyspnœa ceases and the bronchial râles diminish in number. The circulation is not disturbed as it is by the use of diuretin. It remains as it was before the administration of the theobromine. When the pulse has been accelerated or arhythmic it preserves the same conditions; excessive arterial pressure has never been noted.

*Indications and Contra-indications.* The moment that there is any asystole, a profound lack of compensation, a general anasarca, with ascites or pulmonary edema, the instant that digitalin and strophantin, or the direct renal exciting diuretics, caffein or lactose have failed, then should theobromine be resorted to at once in the usual doses. There do not exist in the diseases of the heart, nor in the hemorrhagic or inflammatory complications which accompany them any contra-indications that do not exist for digitalin and caffein.

*Mode of Administration.* As theobromine is insoluble in all fluids, it must be employed in pastilles or cachets containing a half gram or gram of the substance. The first day 2 grams are given in 2 or 4 cachets, taken with food or milk. The second day, 3 grams; the third day, 4 grams; the fourth day, 5 grams. On the fifth day and for the four following days the treatment should be suspended. Then administer 2 to 3 grams daily for three days; in this way the effect received may be maintained perfectly. There can be no habit produced, nor is there any cumulative action.

—D.

## ECTOPIC GESTATION.

A Martin (*Berl. Klinisch Wochen*, No. 22, 1893) has always held the opinion that owing to pathological changes which had occurred in the tube the ovum was necessarily arrested there, in the above condition was always present and acted as the inciting cause. His opinion has, however changed, and he now believes that the ovum can never find a place for any attachment unless the mucus membrane is healthy.

The pelveo peritonitis, so frequently met with in extra-uterine gestation is regarded by him as a secondary complication, incident to the growth of the ovum.

The cases recorded as primary abdominal pregnancy cannot be positively accepted, there being an absence of the necessary proofs. Martin reports a case observed by him in which an ovum of four months had developed on the fimbria ovarica. Further development would have resulted in the implantation of the placenta on the adjacent peritoneum, giving the impression that it had been from the first a primary abdominal pregnancy, while in reality it was of tubal origin.

The author reports five cases of ectopic gestation—tubo-ovarian—four of these were classified as tubal pregnancy, and one as ovarian. Martin explains his meaning of *ovariallube*: an adhesion of the fimbriated end of the tube to the ovary, just at the site of the recently bursted Graafian follicle. This has been previously described by Buxnier.

M. has operated on 61 cases; of these 20 cannot be classed strictly under the head of tubal pregnancy. The remaining 41 he divided into 3 classes.

I. In 14 cases the ovum was found more or less intact in its sac—there was no blood in the abdominal cavity, the ovum being found in various degrees of maceration or resorption.

II. The second group embraces 9 cases of rupture.

III. The third of 16 cases is classed under the head of tubal abortion (expulsion of the ovum through the physiological opening of the tube.

M. does not agree with Werth and Veit whose theory is that the expulsion of the ovum results from a contraction of the muscular fibres of the tube, but believed that its passage is furthered by the hemorrhage which takes place at the seat of insertion of the ovum. —W.

## ANATOMICAL CONSTRUCTION OF SOME OF THE GRANULAR SWELLINGS OF THE INTEGUMENT.

L. Philippson (*Centralb. f. Allgen. Path. u. Path. Anat.*, IV., 1893) extended his studies to the subject of the modus operandi of infection (if internal or external). His observations chiefly embraced syphilis, leprosy, and tuberculosis; his studies resolved themselves into the following conclusions:

I. By infection externally we have, 1. Syphilitic sclerosis; 2. The superficial Lepra-node (?) found in the papillar layer surrounded by healthy tissues; 3. Superficial Lupus-nodes. These are all new growths, situated superficially, having sharp lines of demarcation, more or less round or concentric in form; the deeper structures are attacked later in the course of the disease.

II. Infection arising through the circulation: 1. Roseola, syphilitic papules; 2. Acute erythematous spots, or papules of lepra; 3. Efflorescense in miliary tuberculosis (?). These new growths at the onset, extend in their development throughout all the layers of the cutis, and follow along the ramifications of the blood vessels.

III. By infection through the lymph channels, 1. ———; 2. Superficial nodes of leprosy developed about the cutis; 3. Miliary lupus originating from deep-seated infections. The new growths of the third group, which may also belong to the syphilitic or leprous type, cannot be distinguished by any regular appearance, and are rather plexiform in character.—W.

## EDITORIAL.

### WHAT WE EAT.

If indigestion could be invested with personality, its insidious, untiring, never-ceasing methods of warfare would rank it chief guerilla of the physical department of those Powers of Darkness allied for the destruction of man. In the affairs of humanity unregenerate, indigestion is mixed up more frequently than any other single factor, and further it can disclose more meanness, develop more depravity, inspire more deviltry, and make greater contributions to the sum of human misery. Eager for results and not for reputation, this thing of evil works most effectively, when in combination with grosser evils which can distract the attention and divert the responsibility. The wise man must have overlooked indigestion, when he declared the love of money to be the root of all evil. A commission of modern experts probably, would confirm this decision, but we believe indigestion would receive distinguished mention.

As he progresses in development, man has begun to realize the importance of taking into consideration the influences exerted, and the immediate and remote effects of the abnormal operation of the most important of vital functions. And the variety of phases which indigestion presents is only exceeded by the variety of methods proposed for its cure. The vast majority of so-called cures have one feature in common—inspired of indigestion, they promote the interests of their inspiration.

With the dawning of preventive medicine and sanitary science came new suggestions for eliminating this trouble, and various sophistical methods have, from time to time, been promulgated, which methods in themselves innocuous, have served a good purpose in attracting attention to clues, the development of which has furnished valuable knowledge for the betterment of mankind.

One of the most persistent of these health fads is vegetarianism, a recrudescence of which appears imminent at present.

The vegetarian is a familiar freak, gen-

erally harmless, and the excuses offered for his existence are thrice told tales. We can view his coming and going with equanimity. When he dilates on the horrors of shedding innocent blood for the gratification of unholy appetites, we are indifferent to his kid gloves and leather shoes. When he triumphantly quotes Holy Writ as authority for a comparative test of a vegetable and a mixed diet, and declaims how the young Jewish captives in Babylon lived on pulse and, as a result, for beauty, wisdom and strength far outstripped their companions who were fed from the royal tables, we refrain from seeking an explanation of another event in the same record, wherein monstrous iniquity and blasphemy was divinely punished by restriction to a vegetable diet. Though at first annoyed by a specious exhibit of scientific dilettanteism, we remember his limitations and in silence allow him to relieve his mind.

He explains how mistaken is the idea that heredity or environment exert any influence on the development of an animal, but that food is the determining factor in the evolution of mental as well as physical qualities, and that on diet depends physical symmetry, mental stamina and longevity. He will contrast the forlorn condition of the measly, stray cat, whose carnivorous diet is responsible for its short legs, savage nature and sneaking propensities, with the stately elephant whose diet of herbs has given him huge bulk, great strength and long life.

He assures us that to herbivorous habits are due entirely the excellencies of the mild-eyed ox, and the spirit and strength of the proud horse, and we commend the innate modesty that leads him to omit the addition of the opinionated ass.

When he wanders into the realms of ethnology, we are ready to believe that, mounted upon his hobby, we can see over the head of the flesh-eating Zulu and view the unfortunate effects of a meat diet on the African bushman. We can even select passages from the romances of African explorers which tell the woes of a race of puny dwarfs who are alleged to live by meat alone, and pass over, as flights of fancy, the physical excellencies of the savage cannibals who are neighbors not far distant. We may demur to his claim of recognizing the food habits from the simple appearance of an individual, in spite of the evidence of a diet limited to veal presented by the appearance of the dude.

In short, we submit to his vagaries because we know his intentions are good, and we believe his enthusiasm may aid in arousing attention to an important subject, and thus be useful in securing and circulating knowledge based on ascertained science.

Whether or not, in his pristine innocence, man was an herbivorous animal is of no importance. So far as we have authentic information, man has always been what he now is—omnivorous. The digestive apparatus provided him is so constituted as to require the use of foods of both animal and vegetable origin, in order to maintain a normal physical equilibrium.

The consideration of food in all its phases properly belongs to medicine, and although the subject is but little understood, scientific research has demonstrated fundamental facts sufficient to afford a basis for its intelligent and accurate comprehension. Indeed the question can be reduced almost to the proportions of a mathematical problem.

The subject may be briefly stated in general terms.

Under physical laws, every action of the living animal, from the unconscious performance of vital function to the severest exertion, implies the expenditure of energy. The energy thus expended is derived from the potential energy stored up in the body. Unless the energy used is

replaced, the supply must speedily fail and life cease from exhaustion.

But energy as contained in food is not available until it has been transformed by digestion and assimilation, into the potential energy of the tissues of the body. This transformation requires an expenditure of energy.

It is evident that the proper and healthful diet is the one that economically maintains the normal equilibrium between the energy used and that supplied.

Physiological chemistry has shown that to obtain this necessary energy, the body must be supplied with various inorganic and organic substances, the latter being absolutely essential and presented in three principle classes of compounds, namely: (1) *proteids*, the nitrogen-bearing compounds; (2) *carbohydrates*, and (3) *fats*. The first class, the proteids, are by far the most important to the economy.

These three classes of compounds must bear relatively definite proportions to one another and to the needs of the body. These compounds are found alike in animal and vegetable tissues, but in varying proportions, and in neither animal nor vegetable are they found in the proportions required for use in the body. If they did so appear the typical food would be ready prepared.

In animal food the proportion of the proteids is in excess, while in the vegetable tissue, the carbohydrates are in excess. By a combination of animal and vegetable food stuffs, the proportion of the one to the other may be brought within the limits required by the living being.

This is the barest outline of the factors involved in the determination of proper food for man, and will serve only to hint the principles on which the physician bases his study of food in its relation to man.

It is estimated that the world's cucumbers are worth $8,000,000 annually to the gardeners who raise them, and twice that sum to the doctors and druggists.—*Ex.*

A Clever Dodge.—The publishers of a German novel recently did a neat thing in the way of advertising. They caused to be inserted in most of the newspapers a notice to the effect that a certain nobleman of wealth and high position, desirous of finding a wife, wanted one who resembled the heroine in the novel named. Thereupon every marriageable woman who saw the notice bought the book in order to see what the heroine was like.—*Tit-Bits.*

---

The Doctor Knew.—If some men are sceptical others place an implicit faith in the doctor's prescriptions; and of these was a man in Limerick who went to the undertaker to order a coffin for Pat Connell.

"Dear me," said the undertaker, "is poor Pat dead?"

"No, he's not dead yet," answered the other; "but he'll die to-night, for the doctor says he can't live till morning, and he knows what he gave him.

---

A Courtier.—A little eight-year old Irish boy in one of our public schools was reproved by his teacher for some mischief. He was about to deny his fault when she said: "I saw you, Jerry." "Yes," he replied, as quick as a flash, "I tells thim there ain't much you don't see wid thim purty black eyes of yourn." That was the soft answer that turned away wrath, for what lady could resist so graceful a compliment?—*Selected.*

# ABSTRACTS.

## UTERINE MYOMA.

Twelve months ago a lady about forty-four years old came to me for severe uterine hemorrhage. On examination, I found a large uterine myoma—as large as a man's double fists. No benefit was gained from hot douches, ergot, and as much rest as she could take under her circumstances. I used electricity, but no appeciable benefit resulted. At the end of two months' treatment she was worse off than ever. She went into the Woman's Hospital in my service. The examinations *per vaginam* revealed much solid exudate and tenderness in the pelvis. A laparotomy on her brought to light such dense and extensive adhesions that it was deemed unsafe to attempt to remove the uterus or tubes and ovaries. In this case I determined to adopt a new plan of procedure. I first tied both tubes at their junction with the uterus with a No. 14 silk ligature, using a long curved needle with an eye in the end. This ligature would destroy the functions of the tubes forever and stop blood from that direction coming to the uterus. The uterus was very large and set in solid exudates, like a turnip in frozen mud, and it was feared that even after the tubes were ligated and functionless (though not removed) the blood supply was great enough to continue the hemorrhage. So I adopted the plan of ligating the uterine artery for a half or more of its way down the body of the uterus. Two silk ligatures were applied to the uterine artery as it ascends along the body of the uterus.

As the uterine artery ascends along the body of the uterus to meet the ovarian at the junctions of the tube and uterus, it is tortuous and hugs tightly the uterine body; but one can easily push the needle between it and the body of the uterus and thus ligate it. In some of the fibroid tumors the uterine artery along the body of the uterus enlarges and beats with a tremendous force. Now, this heavy throbbing of the artery is what induces one to attempt to arrest its action, for it does seem that if such a torrent of blood is checked the uterus would not be fed so well.

In my case nearly two-thirds of the way down the uterus the artery received ligatures. The abdomen was closed and the lady recovered. To my great astonishment, the uterus had shrunk to about half its original size in three months. Her profuse hemorrhage stopped and she gained flesh rapidly. Six months after, she was well and the uterus had gone down more than half its original size and felt much more normal in size and shape. Then she appeared perfectly well. Since that time I have done the operation once more, but it is too soon to announce any results.

This new method of operating for uterine myoma consists—1. In ligating the ovarian artery with or without tubal and ovarian removal. 2. In ligating the uterine artery which courses along the sides of the body of the uterus for a half or two thirds its length from the fundus to the cervix. The objects is to induce uterine atrophy and avoid the danger of removal of uterine myoma. The mortality of abdominal hysterectomy for uterine myoma is still very high in the most skilled hands and appalling in the hands of amateur operators. In this operation the mortality over tubal removal will scarcely be increased by the additional time and manipulation necessary to ligate the uterine artery coursing along the body of the uterus. I used a well-curved aneurism needle in performing the operation, thus avoiding the sharp-pointed needle, which might lacerate the vein or artery. One can put the finger and thumb on the artery and feel it beat close to the uterus. A glance at the ever-memorable Hyrtl's representation of the uterine circulation will easily show how the operation can be perperformed. If it be found difficult to secure the corporeal uterine artery in an aneurism, a long, sharp, curved handle needle could be employed, which could be pushed through a part of the uterine substance, if required, to be doubly sure. It is a curious feature that uterine myomata seem to have a very feeble vitality, and by a slight change of blood in some other direction a myoma will frequently shrink. If a uterine myoma can be made to shrink

by a simpler operation than abdominal hysterectomy, the woman is saved from considerable danger and the multilating loss of an organ. Sweeping removal of organs is a backward movement in the art of surgery. This operation will not suit all fibroids, but it seems to me to be a distinct addition to the operation of the removal of the apdendages for "bleeding fibroids" given to us by Battey, Tait and Hegar. This operation is entirely original with me, as I have not observed any note on the idea in literature.—F. Byron Robinson, B. S., M. D., in *N. Y. Med. Jour.*

## URIC ACID DIATHESIS.

Vegetable diet decreases the acidity of the urine, and increases the alkalinity of the blood. Fever does the same thing. Suppose then that a person has a large quantity of the urates in his blood, and the alkalinity of the blood was above normal. At such a juncture he is exposed to wet and cold. As a result, he becomes very feverish, and the alkalescence of his blood falls. It can no longer hold in solution the urates it contains. They are precipitated anywhere and everywhere—around the joints, in the muscles, in the pericardium or endocardium, in the cerebral meninges. Thus we have an attack of inflammatory rheumatism in its varied forms. Just think of your cold baths and alkalies! Use both, and presto the reaction of the blood begins to become more alkaline. The uric acid is taken up, gets back into the blood again, and, by free diuresis and diaphoresis, it is washed out of the system.

If a person has a large amount of uric acid stored up in the system and begins the use of alkalies, and puts himself on a vegetable diet, the acid is dissolved and comes into free circulation in the blood. The effect of this is to make the person feel very ill. A large amount of uric acid in the blood deranges the circulation seriously, and gives rise to severe headache and mental depression. This accounts for the violent headaches that so many experience in conneetion with a uric acid wave. The arterioles are contracted, and the circulation through the brain is decidedly deranged. Certain drugs and acid drinks will throw down the uric acid out of the blood; but at the expense of a reoccurrence of the rheumatic pains in the joints.

It is a well-known fact that during fasting the alkalinity of the blood falls very considerably. Any uric acid in the blood would tend to be precipitated. This fact was specially emphasized by Sir W. Roberts, a short time ago. He made it clear that, to those who are subject to renal calculi, the greatest period of danger is toward morning, when the acid wave sets in. To guard against this acid wave and the formation of renal calculi, he urges that the person should live on a non-gouty diet, should take some digestible nourishment a short time before retiring, and some alkali at bed time. For this purpose he recommends a good dose of citrate of potash in a glass of water. All this is thoroughly scientific. The alkali, in these cases may do good or may do no good, just as it is given at the right time or not.

These cases of dead hands, where the circulation is almost arrested in the fingers, due to contraction of the arterioles, are due to the uric acid diathesis. This distressing condition is an ally of gout. The great majority of those intense headaches of the migrainous types are nothing other than one of the protean forms of the same condition.—*Ex.*

## TECHNIQUE IN TÆNIA TREATMENT—REPORT OF A REMARKABLE CASE.

C. M. FENN M. D., San Diego, Cal.

In the absence hitherto of any unfailing tænicides or specifics, it may be profitable to inquire if there are any other methods available for the safe and certain expulsion of the various cestodes. Personally, having abandoned the search for such a remedy, for the reason that it might imperil the well-being of host as well as guest, I find that some of the standard tæniafuges, if employed in adequate doses and supplemented by attention to certain details, to be noted farther on, may be made to accomplish all that we desire. For example, during the local prevalence of tape-worms which followed the importation of a measly herd from Mexico, some years ago, I came to use kameela in doses of 8 to 12 grains (℥ii-℥iii), and ethereal extract of male-fern to the extent of 4 to 10 grams (℥i-℥iiss). These apparently large doses, exceeding those recommended by the authorities of that period, were successfully administered and upon the hypothesis that a parasite which merely imbibes its sustenance, having neither mouth or intestine, and suckers for prehension only, must require quantity as well as quality. In the matter of details referred to, jalap was selected for the before and after cathartic, in preference to several others commonly used. For instance, castor oil, so widely commended in such cases, was believed to be deficient as a peristaltic persuader and practically inert in the presence of mucus. Senna is equally insufficient in its action and aloes correspondingly tardy, expending its force on the lower bowel. Jalap, on the contrary, besides having somewhat of an anthelmintic reputation is safe and admirably adapted for children, to whom it may be given clandestinely in gingerbread or cookies. Following the last dose of the purgative it is advisable to employ frequent enemata of cold water, with or without salt or soap. These appear not only to chill the worm but to measurably increase peristalsis.

Of the three species of tæniæ which mature in the human intestine, tænia saginata, tænia solium and *bothrinocephalus latus*, the first is of more frequent occurrence in tropical latitudes like this owing, doubtless, to the greater consumption of beef in comparison with other meats.

That tænia solium (pork-worm), however, is not unknown here may be inferred from the following case which may also be considered a fitting résumé of the foregoing remarks:

A little boy, on his first legs, injured a toe, to which his mother applied a bit of fresh pork. A second application, soon required, was about to disappear as mysteriously as the first when he was detected in the act of eating it. Three or four months later during a convulsive seizure several segments of a tænia solium were expelled. Believing it to be an instance of *post hoc procter hoc*, active measures were then taken to relieve the child of his unwelcome guest, and before reaching his third year he passed through ten severe ordeals, expelling in the aggregate 110 feet* of tape-worm! The first three doses, by homœopathic direction, the parents believe were kousso or kameela in combination with some other drug. At all events, after each attempt the child was "sleepy, feverish and a source of great solicitude for twenty-four hours." A fourth dose by another attendant was known to consist of 15 drops of chloroform and one drop of croton oil! This was followed a few weeks subsequently by an emulsion of creasote. Still later, at the suggestion of friends, two attempts were made with emulsion of pumpkin seeds. In justice to all parties, it is proper to state that in every instance starvation and purgation with castor oil, castoria, etc., were rigidly enforced. This is confirmed by an incident in the history, when the little patient led his only sympathetic relative to the cupboard and with tears running down his cheeks exclaimed: "Grandpa, I'se so hungry! I'se so hungry!" Meanwhile, reports of the case had reached relatives in the East, who immediately sent out a quantity of pelletierine tannate, with assurance of success. Two trials of this specific (?) quickly followed

*Measurements reported by parents.

bringing away a few feet of the worm as other remedies had done. A small dose of the pomegranate alkaloid remained, but in view of previous failures it had almost been decided to await the natural demise, or suicide (?) of the parasite at the end of four or five years.

The tenth and successful assault was reluctantly undertaken by the writer. Though I should have preferred kousso or koussin for a child, the remainder of the pelletierine was given.

Without special restrictions as to diet a full dose of jalap preceded the tæniafuge about twelve hours, and was repeated next day an hour or two after the exhibition of anthelmintic. After thoroughly scotching the parasite, indicated by the appearance of large segments in the dejections, frequent enemata of plain and salt water were employed. Traction upon the worm was interdicted, but rather it was advised to strap the protruding extremity to the nates and continue injections. At a later hour the head intact and *erect* with fifteen feet of the tænia gave assurance of its unconditional surrender after a siege of nearly twelve months.—*J. A. M. A.*

## THE TREATMENT OF UTERINE FIBROIDS.

Dr. Augustin H. Goelet, in a paper read before the New York County Medical Association (*Am. Med. Sur. Bull.*, January 1, 1894), says the important question which arises in dealing with these growths is when is interference demanded, and what treatment is indicated. A careful review of the literature of the subject and the opinions of those who are entitled to be regarded as speaking authoritively leads to the conclusion that the majority do not regard the removal of these tumors indicated unless they give rise to sufficient inconvenience to warrant the risk of the operation and the mutilation which involves; that the mortality attending their removal is still too great, even in the hands of expert operators, to warrant its being lightly undertaken. If then it is possible to relieve symptoms caused by these growths, the actual necessity for operative interference is narrowed down to a very small field.

The writer does not agree with certain ultra-gynecologists that these tumors should all be removed when they are small and cause no inconvenience, but he strongly urges that they should be submitted to treatment in this stage, because treatment yields the best results when the tumor is small and of recent growth. The indication for the different methods usually employed are carefully reviewed; electricity, curettement, hysterectomy, and removal of the appendages.

Of electricity he says that frequently a symptomatic cure is all that may be anticipated. The results that may be obtained by this method are classified as follows:

(1) Cure of coëxisting endometritis.

(2) Loosening of adhesions between contiguous peritoneal surfaces.

(3) Relief of pain and pressure symptoms.

(4) Control of hemorrhage.

(5) Arrest and some retrogression of the growth.

The writer takes a bold stand in favor of vaginal puncture, believing it to be perfectly safe if properly done and strict asepsis is observed; that is if as much care is taken with this as with other grave surgical operations. He believes that more success would have followed the use of this agent if puncture had not been abandoned as a hazardous measure. He believes likewise that it is important to discriminate in the choice of the pole to be employed against growths of different structure, just as important in fact as in dealing with such growths as warts, moles and naevi upon the external surface of the body. That is, that when the structure is hard and fibrous the negative pole should be selected, and that when it is soft or myomatous, the positive.

The writer lays stress upon the fact that both subperitoneal and submucous fibroids, when pedunculated are not amenable to treatment by this agent. He positively declares that though assertions to the contrary have been made in some quarters, the proper use of electricity in these cases

does not complicate a subsequent operation for the removal of the tumor; but on the contrary, its use facilitates the removal of adhesions and produces a marked improvement in the general condition of the patient. In fact he often employs it for improving the local condition and for building up the health of the patient preparatory to an operation. It has been asserted that the symptoms return after discontinuing treatment, but the writer believes that when this occurs it is either due to a mistaken diagnosis or a faulty technique which may be unavoidable.

Curettement he thinks is useful as a preliminary measure, but it does not yield a permanent result. In support of this opinion attention is directed to the fact that the mucous membrane removed by the curette is rapidly reproduced and the same causes for the hemorrhage which previously existed still remain. For the control of hemorrhage, when both these measures fails, he advocates ligation of the uterine arteries *per vaginam*, as suggested by Martin, of Chicago. He expresses no confidence in ergot alone in these cases, but regards it as a useful auxiliary in the treatment of certain submucous and soft interstitial myomata when it is desirable to excite uterine contraction.

Goelet believes that the principle indication for hysterectomy is to be found in large subperitoneal and very large and hard interstitial growths which yield little, if at all, to any form of treatment. In these cases, even if the symptoms are relieved, their size is usually a source of so much inconvenience as to warrant the risk of their removal. This operation would also be indicated where treatment fails to permanently control the symptoms, when the tumor is situated unfavorably for treatment and when complicated by disease of the appendages.

Removal of the appendages for the purpose of inducing an artificial menopause which may exert a favorable influence upon the tumor, is not regarded favorably. In his experience as well as that of others, it is productive of very little good, and he strongly urges that when the abdomen has been opened, one should not stop short of removal of the whole tumor unless it is impossible to separate it from its attachments.

**Logic.**

Naming a horse is sometimes fully as difficult as naming a baby, although the groom of a well-known New-Yorker did not find it so the other day. Mr. Johnson had a valuable horse which he had called Ajax, and only recently was able to buy an excellent mate for it. What to call it was the problem, and in his anxiety to discover just the right name several days went by. At last he went to the stable one day and discovered that his groom had solved the difficulty for him. The word "Ajax" was painted over the stall of the older horse, and over that of the new-comer appeared, in large chalk letters, "Bjax." —From the "Editor's Drawer," in *Harper's Magazine* for February.

No More Cheap Neckties.—There is a married man in Detroit whose wife has long assumed the privilege of supplying his neckties. Whenever she came across a "your-choice-for-a-quarter" lot she would lay in a big supply, and the poor fellow always appeared in something that never satisfied his fastidious taste and was sure to be a back number. He bore the thing with Job-like patience until the other day, when he found a job lot of old-time spring hats for ladies. He took the whole outfit, and had them delivered at the house. There was blood on the moon and streaming tears for a time, but peace was finally restored and a contract entered into that the husband should select his own toggery and the wife confine herself to purchasing what her individual wardrobe may require.—*Detroit Free Press.*

An Irishman in France was challenged by a Frenchman to fight a duel, to which he readily consented, and suggested shillalahs.

"That won't do," said the second. "As the challenged party, you have the right to choose the arms, but chivalry demands that you should decide upon a weapon with which Frenchmen are familiar."

"Is that so?" returned the Irishman. "Then begorra! we'll foight with guillotines."—*Brooklyn Life.*

# SOCIETY REPORTS.

## SECTION ON ORTHOPAEDIC SURGERY OF THE COLLEGE OF PHYSICIANS OF PHILADELPHIA.

*January* 19, 1894.

DR. J. B. ROBERTS showed a case of

TUBERCULOSIS OF THE SPINE,

which had been brought to him two years previously.

This case had been treated for two years for psoas abscess with sinuses in the buttocks. He was brought to me thinking that nothing could be done for the boy, as the sinuses were affected by muscular contraction. I took him to the Woman's hospital, opened the sinuses in the buttock and curetted the psoas abscesses, washing them out with iodoform and oil through a tube. I made a section of the tensor vaginæ femorus, the psoas and iliacus muscles and curetted posteriorly, but I feared to make an open wound on account of infection. I put him to bed with extension applied to both legs, and, as you see, his legs are comparatively straight. This was fifteen months ago. About two months since the sinus was still discharging. I made an open incision and made a section of the psoas muscle. I put him in bed in a plaster jacket. There was some suppuration of the wound and on cutting down upon the sinus I found that the abscess was infected from below. The child now walks about on crutches very well, and I show the case as a good illustration of what can be done by section of the tensor vaginæ muscle.

He wore a jacket during the early part of the treatment. My recollection is that the spine was much distorted and very crooked when he was sent to me. To make the spine solid we applied a jacket to the breast.

My own feeling is that the suppuration has now subsided, but I may be entirely wrong, and I shall be glad to have Dr. Taylor's opinion, and that of the Chair as to the need of further active treatment. I am a little inclined to think that he had better be put to bed again with weight and pulley attachments to his feet, if this will straighten him more.

### DISCUSSION.

DR. H. AUGUSTUS WILSON: I was profoundly impressed with this case, as, when we examined it, it appeared hopeless to attempt to improve it; but it now shows the benefit which can be obtained by prolonged and continuous treatment of some of these cases of chronic ostitis. At the time the exploratory operation took place the sinuses were not suppurating extensively, but a considerable amount of softened bone existed at the upper end. I once saw a case somewhat similar to this, but the disease was of longer duration; it lasted for forty years. When the patient kept his bed the suppuration ceased, but within a week from his going about there would be a reaccumulation of pus. I urged an exploratory incision, and one was made in the lumbar region. The vertebral bodies were solid and firm, but half an inch from the original seat of the disease was a spicula of bone three-quarters of an inch in diameter, blocking the sinus almost completely; this would probably keep open the sinus for years. I washed the sinus with peroxide of hydrogen and absolute closure took place. Removel of the bone combined with rest in bed for three months completely closed the sinus.

DR. T. S. K. MORTON: I would like to ask in regard to fixation of the spine until suppuration ceases; whether it decreases or increases under fixation, and whether such fixation causes harm by atrophy of the muscular structures?

DR. WM. J. TAYLOR; I would like to ask Dr. Roberts if he thinks he would gain anything by further operative procedures, or whether by keeping up continuous extension while the boy is up and about—for instance, with some form of splint (such as Thomas') incorporated in a plaster jacket, making the rod quite strong—he would gain an advantage.

DR. DEFOREST WILLARD: My experience is decidedly that fixation lessens suppuration, and I continue it as long as there is any possibility of the evidence of caries. I usually support the child when it is up during the day, and at night again apply extension without the jacket.

The experience of the chair is that the longer the period of extension, the greater the gain. The cicatrices must be elongated as much as possible, otherwise contraction will occur from the nature of the flexors. Osteotomy may be advisable two or three years later, after the general health has been established. I should hardly think that any further operation, so far as section is concerned, would accomplish much at present. Is not mechanical fixation desirable until

suppuration ceases? Does it not prevent the formation of pus?

---

Dr. John B. Roberts read a paper entitled

A CASE OF PRIMARY TUBERCULOSIS OF THE LAMINÆ AND SPINOUS PROCESSES OF THE VERTEBRAL COLUMN.

The great rarity of this condition induces me to report the case and show the specimen. A girl of about ten years, was admitted to the Jewish Hospital in July 1892, stating that three months previously she had fallen down two steps. The exact history was difficult to obtain because of her ignorance of any other tongue than Russian. She became paralyzed in the legs shortly after the slight injury mentioned. It was difficult to determine whether any relation existed between the slight injury and the paraplegia, as one account of the fall seemed to indicate that it was due to heat prostration. When the child was admitted to the hospital there was no marked deformity of the spine. The paralysis of both legs was complete, both of motion and sensation, and bed-sores existed. Subsequently, swelling about the middle of the dorsal region appeared, but it was evident that this was not the ordinary kyphosis of tubercular disease of the vertebral bodies. The swelling was most marked on each side of the median line, being greater on the right than on the left. Believing that the case was one of tuberculosis of the laminæ, and that there was probably an abscess within the spinal canal, I determined to do a laminectomy. An incision was made in the swelling on the right side of the vertebral spines, from which a small amount of cheesy material, some small fragments of bone, and a considerable quantity of fluid blood escaped. The blood was dark in color and seemed to come from an active venous hemorrhage. The swelling on the left side consisted of a mass of tissue infiltrated with tubercular deposit. The patient died on the table from shock and bleeding, though the bleeding seemed to come only from veins and was not excessive, though it was quite free. Before the patient succumbed I had removed two vertebral arches which were so soft that the ordinary scalpel cut through them with ease, except in one place where I used the chisel. The spinal cord was flattened, but I could easily pass my finger into the vertebral canal above and below. This showed there was no pressure, except at the point where was situated the tubercular swelling, and the hæmatoma was apparently due to the opening of the vein by the disease. I removed a section of the spinal column, examination of which, as will be seen by looking at the specimen before you, shows that the tubercular disease was limited to the laminæ and had not attacked the bodies. The primary disease, therefore, is in the posterior arches of the vertebral column, instead of in the bodies, where it usually is found. A pathological examination made by Drs. Coplin and Bevan, proves the destruction of the bone to be due to tuberculosis. The bacillus was found in abundance.

DISCUSSION.

DR. JAMES K. YOUNG: This specimen should not be permitted to pass unnoticed. The position of the disease is certainly a rare one. Tuberculous process of the spinal column usually commences, so far as I am informed, in the bodies of the vertebræ, and in cases where it begins in the laminæ, it is due to traumatism, usually from fracture. But one similar case has come under my individual attention and in this traumatism was an important factor. If the disease had commenced in the posterior part of the body it might have secondarily involved the laminæ, but it usually commences in the anterior part, and this is the reason why the laminæ are so rarely attacked.

DR. H. AUGUSTUS WILSON: I think Dr. Roberts' was very wise in drawing attention to the clinical features of this case. When it was decided to lay open the abscess, the tumor on the right side had all the clinical appearance of being a very soft and fluctuating abscess; whereas the hard tumor was, or rather seemed to be, a mass of tuberculous fibrous tissue. The clinical features made me approve of Dr. Roberts' intention to evacuate the abscess. I was surprised to find when the abscess was opened that it was a blood cyst. This only shows that we cannot be sure of what is under the skin, and it reminds me of a remark of the late Dr. Gross that we can be pretty sure by inspection, but cannot be positive until an incision is made.

DR. WM. J. TAYLOR: I have seen one case of laminectomy which was done for fracture, but so far as I can recollect the laminæ of the 4th, 5th, and 6th were removed at the time of the operation. The man died in twenty-four hours. At the post mortem it was found that although we had removed the 4th, 5th, and 6th, the 3rd was perfectly solid and in good condition, but the second was fractured. This was a case where secondary operation would be justifiable. The man was crushed by falling coal. There was one of the bones in absolutely good condition, but above and below it fracture existed.

DR. DEFOREST WILLARD: I recall a similar case now under my care—a young man from eighteen to twenty years of age. After a slight blow upon the back, he began to have rigidity and presented all the clinical appearances of spinal caries; there was no kyphosis, however, although the disease had

existed for a year. There was a soft prominence between the scapula in the mid-dorsal region from the fourth to the eight, which was very peculiar, and I believed it to be spinal abscess from caries. Instead of a prominence over the spinous processes there was such a depression that I could carry my finger down deeply. I considered this decidedly a case for operative procedure although there was no paraplegia. I laid open the abcess and discharged a pint of pus. At the bottom of this cavity I explored the vertebræ and found two laminæ lying loose, the sixth and seventh. I gnawed away the eight and also the fifth, which was greatly eroded. There was no appearance of disease of the bodies. Suppuration continued for a long time. I operated a second time, four months later, and finding another lamina carious, removed it. The wound is still open, but I have not seen the case for two months. I understand that the young man is still living, but as he has tuberculosis of the lungs it is not probable that he will last long. It was evidently a case of primary tuberculosis of the laminæ and spinous processes. I do not think there was any marked disease of the body unless it has extended. There was no evident pressure upon the cord.

There is one point in the case of Dr. Robert's, which occurred to me; it is in reference to shock. I have never seen a case of laminectomy in which there was not an enormous amount of shock. Some authors say that it is an operation not attended with great danger; but in my experience, it is an exceedingly serious one. The moment that a finger was placed upon the spine, in the case before alluded to, we thought the man would die; respiration was interfered with, and the shock was so evident that we were obliged to use artificial respiration, injections, etc., to keep him alive. In my experience I have found that all manipulations of the spinal column should be avoided. I shall be glad to hear from the other members as to this point.

---

TWO CASES OF CONGENITAL HYPERTROPHY.

DR. THOMAS S. K. MORTON made some remarks upon the subject of congenital hypertrophies of the extremities and reported two marked cases of such hypertrophies of the hand.

The first case occurred in a child aged 18 months. The index and middle fingers of the right hand were enormously hypertrophied in all their elements, while the remainder of the hand was normal. Almost no function existed in the affected fingers. Amputation was resorted to, successfully, at the metacarpo-phalangeal articulations. Microscopic examination showed that all elements entering into the diseased fingers were hypertrophied by a fibro-fatty degeneration. The joints were but poorly evolved.

The second case was that of a child 22 months old. Here the hypertrophy involved the entire hand and lower portion of the forearm and was accompanied with venous engorgement and marked varicosity. There was a deep groove at the middle of the forearm, as if the umbilical cord might have been tied about the member. The hypertrophy in this case was limited to the skin and subcutaneous tissues and did not interfere with function markedly. There was no hypertrophy of the bony or cartilaginous elements. Great improvemt had resulted from the application, for months, of twenty per cent of ichthyol in lanolin under considerable bandage pressure and an ultimate cure looked forward to. The varicosity and venous engorgement had largely disappeared already.

---

Dr. George Erety Shomaker, read a paper entitled

CONGENITAL HYPERTROPHY, WITH REPORT OF A CASE OF CONGENITAL HYPERTROPHY OF THE FOOT.

with report of a case of congenital hypertrophy of the foot.

In diagnosis care must be taken to separate the condition from atrophy of the corresponding part; from acromegaly; angiose enlargement; myxœdema; various arthropathies and from skin hypertrophies, as sclerodema neonatorum.

The case reported was undoubtedly congenital. The girl was 19 years old. One brother had a supernumerary thumb. She had hypermetropia, internal strabismus, an infantile uterus, very marked hystero-epilepsy with opisthotonos during the convulsions.

The hypertrophy involved the outer two-thirds of the left foot and involved skin, subcutaneous tissue, muscles and bone. Operation by amputating enlarged toes and dissecting away muscle and hypertrophied skin and connective tissue, gave a satisfactory result.

DISCUSSION.

DR. H. AUGUSTUS WILSON; I would like to say in reference to the etiology that the theory of arrested development seems to me to be the most reasonable explanation of all the deformities occurring prior to birth. The musculo-nervous theory is unsatisfactory in that it explains only some of the congenital deformities, and sometimes it will possibly explain the pre-occurrence of an atrophy when there is present, in the same body, some other deformity, for instance, a intra-uterine amputation.

DR. WM. J. TAYLOR: I had a case of peculiar hypertrophy of the foot in a child a year old.

The child was brought to a meeting of the Neurological Society and was seen by Dr. Mills and Dr. Willard. Some discussion arose as to the diagnosis. The whole of the foot was enlarged. The cast exhibited by Dr. Morton brought the case to my mind. In this instance it was the left foot in which two of the toes were much enlarged; also the great toe, but the remaining toes not so much in proportion.

I have not seen the case for many months. In looking over some papers I came across a rude drawing of the foot, as I was unable to obtain a cast or a photograph as the child was so active. I attempted to make a wax impression but even in that I was not successful. I will see the child and if possible bring it here to show it to the members. Nothing was done in the way of treatment on account of the uncertainty of diagnosis.

DR. G. ERETY SHOEMAKER: In regard to the point just raised by Dr. Morton, we are able to say, definitely in some cases, that it is not due simply to pressure; for instance, when one-half the jaw or one-half the face is hypertrophied, or where the outside portion of an extremity is involved, we must look to a central and, in the case of the face, a cerebral origin. Yet this is saying little, as we know nothing of the ultimate processes which result in trophic changes.

An autopsy should be of great interest if brain sections were made. The value of such an investigation would be much greater, however, in the infant than in the adult, because disuse alone of the hypertrophied or atrophied part would, in time, produce secondary degeneration at the corresponding centre, which might be mistaken, in an adult, for congenital defects; while in the case of the infant no such secondary degeneration could have occurred for lack of time.

# CURRENT LITERATURE REVIEWED.

IN CHARGE OF ELLISTON J. MORRIS, M. D.

THE AMERICAN JOURNAL OF OBSTETRICS for February. Dr. Francis Foerster continues his interesting series of papers on

**Comparative Microscopical Studies of the Ovary,**

this number being devoted to the consideration of "Small Cystic Degeneration of the Ovary." He sums up the results of his researches as follows:

1. Small cysts are of common occurrence, not only in human ovaries, but also in those of the sow, ewe, and the cow.

2. In accord with the researches of Nagel, the author is convinced that the small cysts are original Graafian follicles.

3. In a process not exactly pathological the stratified epithelial lining of the Graafian follicle undergoes peculiar changes leading to its disappearance.

4. The epithelium first breaks up into an indifferent or medullary tissue, and from this arises myxomatous vascularized connective tissue.

5. The type of the newly-formed myxomatous tissue varies in different animals. It may be medullary myxomatous, or myxomatous lymph tissue, or fully developed myxomatous tissue with a well-marked basis substance.

6. The newly-formed myxomatous tissue is always scantily supplied with blood vessels, which probably grow into it from without.

7. The myxomatous lining of the cyst-wall is always well defined toward the outer fibrous coat, the original capsule of the Graafian follicle.

8. The ovule is present at the beginning of the formation of a small cyst; later it probably perishes, owing to the changed environments.

The paper is illustrated with woodcuts of sections of ovaries showing the appearances spoken of by the author in the article.

Dr. Karl Sandberg contributes an article on

**Symphysiotomy,**

reviewing the opinions of the various advocates of the procedure. The literature of the subject has been thoroughly studied by the author and the views of the operators in this country and abroad are carefully set forth. Faulty union of the pubic bones, resulting in impaired locomotion, was one of the great objections to the operation in its early period. Since its revival, and especially during the last six or seven years, failures in this respect are almost unheard of, whether the operator applies bone sutures or only keeps the divided bones in apposition by a firm bandage. The author believes that if the subcutaneous method of operating be chosen, the soft parts should be loosened by the operation from the pelvic walls on both sides far enough to allow sufficient stretch, and thus serious injury to the soft parts will be avoided. As to the mathemetical limits for symphysiotomy, they can be figured out for a child of normal dimensions. As the biparietal axis of the head is 9.5 centimetres, and we can depend on a gain of 2 centimetres by the symphysiotomy and 0.5 centimetre by compression of the head, a conjugata vera of 7 centimetres will be the minimum limit for the operation. The maximum limit, according to most authors, should be placed at a conjugata vera of 9 centimetres for a flattened pelvis and a maximum limit for a generally contracted pelvis of 10 centimetres. The author is of the opinion that symphysiotomy is naturally destined to assume a position between high forceps delivery on the one hand and Cæsarean section on the other, and is a direct competitor with craniotomy and induced premature labor.

Dr. Adolph Rupp discusses

**Aphthæ and Diphtheria.**

"The object of this paper is to call attention to the fact that although most if not all of our text books scarcely comment on the association of aphthæ and diphtheria, these diseases do occur 'side by side' or concurrently; and secondly, although typical manifestations of aphthæ can hardly be mistaken for diphtheria, even after a hurried or superficial examination, in most cases, occasions are not wanting when the mistake may be made by tolerably careful observers; and lastly, when the two diseases co-exist in the same patient, aphthæ may manifest themselves before the symptoms and signs of diphtheria have done so, and thus the benign malady will more or less mask the serious disease."

Dr. G. William Reynolds reports a case of

**Pyometra.**

The patient was fifty three years old and the mother of ten children. The menopause had occured one year previously. There was an increase in size of the abdomen with bearing down pains accompanied by distress in the vagina and rectum, with great vesical irritability. There was a sense of mallaise, attended with slight chills, and more or less pain in the hypogastrium. Temperature on admission to the hospital was 98°, pulse 80 and normal. The tumor was regarded as a fibroid by most of the physicians who saw her. The credit of the correct diagnosis is due to Dr. Senn, who upon digital examination, discovered obscure fluctuation, and suspected, on account of the age of the patient and the history of the case, that there might be pus in the uterus. This suspicion was based largely upon the fact that no trace of cervix or the cervical canal could be found even when searched for by means of a large Sims speclum. The correctness of the diagnosis was proved by the finding of an abund-

ance of pus upon vaginal puncture of the uterus with a small sterilized trocar at a point corresponding with the obliterated cervix. The uterus was incised by means of the thermo-cautery as nearly as possible in the normal situation of the cervix. The thermo-cautery was used to avoid serious hemorrhage and because it would leave the opening less liable to close permanently by cicatricial contraction. More than a quart of pus escaped. After a through irrigation with saturated boric-acid solution, a half-inch fenestrated drainage tube, about six inches in length, was passed into the uterine cavity, which was about ten inches in depth. Iodoform was used freely, the vagina packed with iodoform gauze and the usual external antiseptic dressings applied. The dressings were changed daily and the uterine cavity irrigated with an antiseptic solution. As the uterus contracted the drainage tube was shortened. She left the hospital perfectly well three weeks after the operation. It is probable that this pathological condition began at or about the time of the last confinement, fourteen years previously, at which time occurred a prolapse of the uterus and laceration of the cervix, with ectropion, followed by ulceration, cicatrization, and closure of the cervical canal. After a thorough and exhaustive study of the literature at his command the author has not been able to find a case identical with, or even strongly resembling, this one.

Dr. George Byrd Harrison contributes a paper entitled

**Points in the Etiology and Treatment of Infantile Eczema.**

The anthor believes that unguents are better than lotions in the treatment of the disease and that they must secure exosmose more surely than lotions, even of the specific gravity of the serum. A most important point in connection with constitutional treatment is that the remedies most commonly used (notably arsenic) are cutaneous stimulants, and their doses should be graduated inversely as the degree of cutaneous irritation, or rather inflammation. He believes that viola tricolor, calcium sulphide, rhus toxicodendron, and numberless other agents generally used, are liable to the same rule of exhibition. When the local lesions of eczema exhibit highly inflammatory conditions the most minute doses of these alterative agents are found to have the best effect. In regard to local applications, where inflammatory action is high they should be protective and soothing; on the other hand, when indolent, most stimulating agents and measures may be employed to alter secretion and promote absorption.

Dr. L. H. Dunning described a "Placental Extractor," and Dr. F. Byron Robinson contributes a short letter on "The Functions of the Omentum." He takes exception to Dr. Ross' statement in the December number of the journal that peritonitis does not occur in dogs and horses and concludes from his observations that the omentum in dogs serves the same purpose as in man: to prevent the invasion of infection, to prevent the adhesion of the gut to the abdominal parietes and to facilitate visceral movement.

The remaining papers in this issue are: "Disputed Points in the Surgery and Pathology of Pelvic Disease," by Dr. Joseph Price; "Neurasthenia in Young Women," by Drs. Henry B. Deale and S. S. Adams; and the conclusion of a paper by Dr. Anna M. Galbraith, entitled "Poliomyelitis Anterior Acuta Infantilis."

---

REVIEW OF INSANITY AND NERVOUS DISEASES for December, 1893. Dr. Frank Parsons Norbury writes on

**Insanity in its Relation to Life Insurance.**

The author dwells on the necessity of recognizing insanity and kindred affections early in their course; and on the need of greater attention being paid to these subjects in medical schools.

Cases of this class, dying shortly after successfully passing insurance examination, show the careless way in which these examinations are sometimes conducted. The author criticises companies which avoid the results of this neglect by declaring the policy of a suicide void, as suicide may be regarded as pathognomonic of insanity, and deserving the same regard as any other cause of death.

Dr. Horace N. Brown describes a case of

**Delirium Grave,**

Bell's Mania, and gives Osler's definition: "An acute delirium running a rapidly fatal course, with a slight fever, in which post mortem no lesions are found of sufficient gravity to account for the disease."

The patient was a young man, about 24 years old, who had been feeling unwell for three or four days. He had frontal headache, slight epigastric pain, and was lying in bed in a profuse perspiration, with anxious look; pulse of 84, temperature 100.8°, eyes sunken, pupils sowewhat dilated, face pale, and there was a very strong odor from the perspiration. The respiration was about 24, irregular and sighing, and complaint was made of the throat closing, so that he could not swallow. When apparently unobserved he swallowed without much trouble. He slept poorly, and had no movement of the bowels for six days; the colon was loaded with feces. The throat was normal. One grain of calomel at night, followed by a saline in the morning, was ordered and seemed to have relieved all trouble, as the temperature and skin seemed normal. Urine was normal in amount and free from albumen. Physical examination showed nothing abnormal. Still complained of difficulty in breathing and in swallowing.

The author left town the same evening and next morning found the patient dying. His arms were scratched and bleeding, pupils dilated, tongue protruding, and the general condition of cyanosis. Until the previous afternoon there seemed to be improvement; then he seemed greatly excited by the visit of a friend, finally calmed down, but in a few hours became wildly delirious, with marked delusions of grandeur and self-glorification. The

tongue became swollen, the mouth full of ropy mucus, water was called for and swallowed with difficulty. The respiration seemed obstructed. The tongue seemed tremulous, the conjunctivæ injected, and the cornea glassy. The patient dashed himself around regardless of injury, and grasped at his throat as though it were obstructed. His body was covered with a cold perspiration. During the attempts at speech the words were disconnected and irrelevant.

The diagnosis of those who saw the case at this stage was hydrophobia. No history confirmed this, and there was no family history of insanity. At the post-mortem it was not permitted to examine the brain, and the other organs were found in a normal condition.

The most notable characteristics were the resemblance to hydrophobia, the low temperature and the rapid fatality.

In hydrophobia, the premonitory symptoms, anxiety, depression, social aversion, spasm of glottis and larynx would be similar but more marked. In hydrophobia the delirium is intermittent, and instead of being delirium of grandeur is peevish, and the patient appears trying to escape an unknown danger. It is interrupted by convulsive attacks causing dyspnœa, dysphagia, etc., and spasm of the glottis causes moans to sound like the barking of a dog.

Writers on the subject seem to agree that the cause is some poison formed during imperfect digestion. Post mortem the meninges and gray matter show some imflammatory changes.

The author describes the typical disease at length, showing the gradual changes that take place in a case, lasting as they usually do from ten days to three weeks. The one now reported being the only known case lasting less than three days.

The differential diagnosis from acute mania rests mainly in the prodomes of the mania lasting a number of weeks with no perversion of digestion or appetite and an apparent system in the ravings. In acute delirium this is all reversed. The onset is sudden, digestion and appetite completely deranged, and the delirium is without system.

The high temperature, at the onset, in sunstroke distinguishes it, while the condition of urine, heart, pulse, fundus of eye, and the odor of the sweat distinguished uræmia.

In treatment all efforts must be directed to calming and supporting the system. Removal to an asylum, and the use of bromides, chloral and hyoscine are mentioned, different men advising different drugs. Ægotine and digitalis may be called for, to sustain the heart. Fluid foods, either by mouth or rectum, are indispensible.

Death results in eighty per-cent. of cases, and complete recovery, without physical or mental sequels, never occurs.

Dr. Poncet reports a case of "Myxœdema," with great physical, mental, and moral depravity which he relieved by thyroid erethism. He made a median incision in the neck, found a poorly developed thyroid gland, and raised it, scraped it with his finger, and dressed it with iodoform. The good effect was very great, the myxœdema disappearing and the patient becoming "docile, modest, diligent, and trustworthy."

Another article mentions varying degrees of success in operating in various ways on Exopthalmic Goitre, showing that there is some hope of relief, if not of cure, in these cases.

Dr. F. Velten is quoted as claiming potassium iodide to be a specific in epidemic cerebro-spinal meningitis. He administers three to six grammes daily and has used it many times. He thinks it would have the same effect in pneumonia, owing to the similarity of the cocci.

Dr. F. S. Davis advocates instead of venesection in purperal eclampsia the use of one-third grain of morphia, six drops each of alcohol and tincture of veratrum viridi with thirty minims of water. It produces, he says, relaxation, moist skin and slow pulse. Five cases treated recovered, one requiring a second injection.

In the *Deutsch. Med. Wochensch.* is mentioned a case of salivation due to loss by operation, for infiltrating chancroid, of the lower part of the second and third frontal convolutions. This resembles salivation in microcephalia with rudimentary frontal convolutions.

In the same journal it is mentioned that the appearance of herpes labialis seems to show a local infection, and in cases of meningitis seems to exclude tubercle as the cause, even in cases of known tuberculous antecedents.

Paralysis of the laryngeal muscles is mentioned as a sign of great diagnostic value in tabes dorsales, and a laryngoscopic examination, therefore important in making a diagnosis.

Genhardt names tabes dorsalis as a hitherto unmentioned cause of diaphragmatic paralysis. He gives the history of a case.

In the *Chicago Medical Standard* Dr. Lyman writes of the failure to recognize certain marked forms of rheumatism; transient, vagrant, disorders of brief duration occurring in elderly nervous persons of arthritic diathesis.

A universal prickling over the skin may interfere with sleep, and may resemble a flea bite, etc. Irritation of the superficial nerves of the scalp may occur. These attacks rarely last more than one day.

Various sensations may be felt in the fauces, Eustachian tube, tongue, etc. It sometimes resembles genuine neuralgia in intensity, and may be very persistent in those having gout or diabetes, and in obese persons. A paroxysmal cough with headache occurs, but perhaps the most annoying symptom is gastralgia.

---

JOURNAL OF CUTANEOUS AND GENITO-URINARY DISEASES.

Dr. Charles W. Allen describes a case of

**Gangrene of the Scrotum,**

in a man 34 years of age, a free user of alcohol.

Almost all of the tissue was involved, and sloughed off, leaving the testicles quite exposed and a peculiar brick-red in color; even the tunics of the left testicle were involved and sloughed somewhat.

When first seen, the case had been neglected for eight days, owing to the patient's intoxication. Until the slough came away, hot charcoal poltices sprinkled with iodoform were used. Afterward aristol and traction strips were applied to such remnants of scrotum as were left. The result was a new scrotum, and the discharge of the patient six weeks after admission.

The report shows how much may be accomplished by patient care in a seemingly hopeless case, and the author writes in the hope of preventing castration in such cases, instances of this needless operation having come to his notice. Constitutional treatment does not seem to have been required here.

The cause of the disease was not known; but it may have been infection through a partially healed bubo, or indirect violence from heavy lifting.

Dr. Frank Lydston, treats of

**Hemorrhagic Emissions.**

The author states that although the literature on the subject is scanty, he has been called on, not unfrequently, to treat the trouble. In some cases the bleeding occurred at the time of sexual intercourse, and occasionally reappeared at intervals for days; in other cases it came on with nocturnal emissions.

Several cases are cited and the conditions in each given. There seems to have been prostatitis with seminal vesiculitis, or else urethral congestion due to strictures present in all.

Irrigation of the deep urethra, irrigation of the rectum with hot water, sexual hygiene, and when required, the internal use of bromides, ergot, gelsemium, etc. The strictures were dilated, if necessary cut, and as soon as the parts would bear it, cold sounds were introduced.

Dr. Willard Parker Worster treats chancres by spraying, daily, with about one ounce of 15-volume solution of peroxide of hydrogen, under 60-pound pressure, and dressing with iodol. He claims good results, and absolute painlessness for the method. The pressure of 60 pounds he thinks very important. All instruments, of course, must be non-metallic.

---

THE NEW YORK JOURNAL OF GYNECOLOGY AND OBSTETRICS

for February 1891, contains an article by Herman J. Boldt, M. D., on the

**Ligation of the uterine arteries for the cure of Fibro-Myomatous Tumor of the uterus.**

He considers this an operation of much promise and free from danger The credit of this plan of operating is due to an American, Dr. M. B. Dorsett, whose first publication on this subject was in August, 1890. Martin, however, seems to have been the first to put this form of treatment into practice in this country; and his method is to ligate *en masse*. The author reports a case in which the technique of Martin is followed, with this exception, viz., that the cul de sac of Douglas is opened so as to allow the index finger to be used as a guide in ligating the uterine artery. The opening of course is closed when the operation is complete. If after two months there is no amelioration of the symptoms hysterectomy should be resorted to. The author limits the application of the method to tumors which do not reach a size larger than sufficient to extend two or three fingers breadth above the symphysis. Suppurative disease of the amexia is a contra-indication to the operation.

Dr. G. M. Edebohls gives a

**Report of Five Cases of Acute Appendicitis,**

and remarks on two or three features of the cases only. Two of the cases were of acute gangrenous appendicitis with perforation—a class doomed to a rapidly fatal issue by any treatment except the knife, and that promptly resorted to. The only point of technique touched upon was the matter of irrigating the peritoneum. He felt that there was greater danger of spreading the infection by irrigation than by dry cleansing. As to chronic cases he says that the time has come when we shall deal with this class of cases just as we deal with chronic salpingo-oophoritis, i.e., on objective and on subjective indications alone. A feature of special interest is the reciprocal relation existing between the appendix and the right uterine appendage, as illustrated in two of the cases.

All made a good recovery.

The question of

**Early Catharsis After Celiotomy**

is discussed by Joseph Brettaner, M. D. His conclusions are:

1. In the vast majority of our cases of celiotomy it is a matter of absolutely no consequence if the bowels are moved early or not. Our good results depend solely on perfection in the operative technique and asepsis.

2. In those cases in which early attempts to move the bowels have failed, persistent efforts to produce catharsis should not be made, but on the contrary a dose of opium (morphine) is indicated.

3. In those cases in which we have employed iodoform gauze to exclude the field of operation from the general peritoneal cavity, to prevent infections, it is in his opinion decidedly bad practice to attempt early catharsis, but we should rather wait until the sign of the restitution of normal peristalsis has been given—that is the spontaneous escape of gas per rectum.

Dr. Geo. W. Cale contributes an article on

**Celiotomy for Strangulated Ovarian Cysts.**

Among the causes for rotation of the cyst the author states that long pedicle is one of the prime factors. Repeated displacements by passage of feces along the sigmoid flexure was assigned as a cause by Mr. Tait. It is a well known fact that this accident often complicates pregnancy, and especially is it apt to occur after delivery. Slight rotation may give rise to little or no effects; more complete

rotation may cause atrophy, rupture or gangrene of the cyst. Inflammation may also occur. These symptoms are apt to follow sudden twisting. Complete detachment may occur in cases of gradual twisting. These, however, are rare.

The symptoms of strangulated ovarian cyst are sudden and violent pain in the abdomen, vomiting and shock. The tumor may be changed in position, and possibly grow rapidly large. These cases are to be distinguished from ruptured tubal pregnancy, internal strangulation of the bowels, gallstone, colic, perforated appendix, etc. Following is the report of an acute case with operation and recovery.

James A. West, M. D., furnishes an article on

**Pyelitis and Pyonephrosis in Women, with a Report of the Case of Each.**

The cases are of interest because both recovered, and because they represented two different methods of nephrectomy, viz., extra-peritoneal or lumbar nephrectomy and transperitoneal or abdominal nephrectomy. Among the causes the author enumerates pyæmia, renal calculi, tubercular infection, pelvic growth obstructing the ureters, cystitis, which is most important. It is often difficult to determine whether the pathological process begun in the bladder or the kidneys for the symptoms are somewhat similar, and indeed the diseases are generally associated. The cachexia of chronic suppuration, anorexia, nausea and vomiting, temperature of septic absorption and attacks of renal tenesmus may be common to both diseases. In pyelitis pain in the lumbar region is a marked and almost constant symptom. If the disease be due to renal calculus, the attacks of renal tenesmus will be very severe, pain extending down the course of the ureters into the bladder, hip and thigh of the affected side The attack is often ushered in by a well-marked chill, and accompanied by considerable elevation of temperature. Gravel in the urine is not of diagnostic value, nor is the epithelium of import. In the case reported the bladder was thoroughly irrigated, and the urine allowed to collect for a few minutes. A large quantity of pus and epithellum was found. This, coupled with the pain and renal colic in the left side led to the diagnosis of pyelitis. If the disease be far advanced a tumor may be mapped out, the diagram may be rendered certain by catheterization of the ureters by the method recently perfected by Kelley.

The method of catheterization practiced by Bozeman is yet more direct. He makes a large opening in the base of the bladder in the region of the ureter and brings it under direct observation. Through this opening he is able to irrigate the pelvis of the kidney with an antiseptic solution. The opening is useful, also, in cases of cystitis, by affording free and constant drainage from the bladder. In cases where disease of the kidney is not too advanced, it is an ideal method. If in performing nephrotomy the kidney is found to be diseased to such an extent that it may not be restored to usefulness, at a later day nephrectomy may be performed. Nephrectomy is always to be resorted to as a last measure to save life. Following is the report of the two cases.

# PERISCOPE.

## THERAPEUTICS.

### A Simple Remedy for Coryza.

In the *Review Medicale*, the following is given as an excellent remedy for coryza. A ripe lemon is taken and some of its juice is squeezed into the palm of the hand. The juice is then forcibly inhaled up the nostrils. Two or three such inhalations will suffice, it is said, to cure an ordinary cold.

### Nitro-Glycerine in Sciatica.

Dr. Lawrence reports the case of a carpenter, age 52, who suffered several weeks with sciatica. In order to relieve the pain he had become a morphine user and could not abandon the habit. After trying a multitude of drugs he gave him a 1:100 solution of nitro-glycerine, one drop three times a day, gradually increasing the dose to five drops. Relief was almost immediate and in ten days he could resume his work, completely cured. —*Revista de Ciencias Medicas de Barcelona.*

### Diphtheria Conveyed by a Toy.

In a case of Diphtheria occurring in a child, Abel (*Centrallb f. Bakl.*) had an opportunity of examing bacteriologically the article, (a wooden toy) suspect of harboring the contagion. Portions of the article were washed in sterilzed broth, and from this serum and agar tubes were inoculated and guinea pigs injected subcutaneously. The tubes showed in addition to various organisms, bacilli which resembled in all respects those of diphtheria. The animals died with all the symptoms of that disease and diphtheria bacilli were found at the seat of inoculation. This is the first time, as far as Abel is aware that the specific organism has been found in the object suspected of conveying diphtherial contagion. Circumstances proved that the article could have been infected only on two occasions, nine years and six months respectively, before the investigation. A review of published observations on the subject shows that the former is far too long a period for the duration of infection in diphtheria. Especially valuable in this respect is the experience of Norwegian physicians, since in Norway with its scattered population and limited traffic, the sources of error which obtain in more densely populated countries can be in larger measure excluded. Norwegian records bear out the most reliable

observations made elsewhere, in fixing one year as the longest period during which the contagions of diphtheria can exist in fomites. Abel observes that the fact, pointed out by Loeffler and others, that virulent diphtheria bacilli are to be found in the fauces of patients during the first month of convalescence from the disease, points to the possibility of infection of objects sometimes after the subsidence of the actual malady. In conclusion he emphasizes the necessity for thorough disinfection of the patient's secretions and excretions, and of all objects which have come into contact with him.

### Saline Laxative.

Constantin Paul recommends phosphate of sodium as a substitute for sulphate of sodium. He gives it in the form of lemonade. It does not gripe. The following formulæ are used:

℞ Distilled water.....ʒvj
Phosphate of sodium.....ʒvi¼
Essence of citron.....gtt. xx.
Syrup.....ʒij.—M.

℞ Distilled water.....ʒviij
Phosphate of sodium.....ʒvi¼
Essence of citron.....gtt. xxv.
Syrup.....ʒij
Citric acid.....
Bicarbonate of sodium.....āā ʒiss.—M.

An effervescing mixture.—*Le Prog. Med.*

### Ichthyol in Fissure of the Anus.

Dr. A. Van der Willigen, of Rotterdam, has found this remedy very useful in the complaint mentioned, cures being brought about in from eight to ten days. He gives liquid food and small doses of castor-oil during the progress of the treatment.—*Provincial Medical Journal.*

### Acute Coryza.

℞ Camphor.....gr. xx
Cocaine mur.....gr. xv
Bismuthi subnit.....ʒss
M. Sig.: Use as snuff.

—Prof. Waxham, in *Gross Med. Coll. Bull.*

### Cocaine in Small-Pox.

Dr. Samayoa, of Guatemala, after using this alkaloid in several cases of small-pox, states his results as follows:

Cocaine given continuously from the beginning can completely abort the disease.

If given after the eruption has appeared, it will transform confluent or hemorrhagic into discrete forms.

Sometimes when the cocaine is given from the beginning of the disease, the eruption assumes a corneal aspect and the pustules fall very soon.

Cocaine prevents suppuration, hence there is no secondary fever, and no marks remain on the skin.

To obtain these results it is necessary to give cocaine as soon as the initial symptoms appear, *and it must be continued without interruption.*

The best preparation is the hydrochlorate, and should be continued five or six days or even nine if necessary.—*La Escuela de Medicina.*

### Condensed Milk.

In many places, the milk supply is of very doubtful quality. Often it will be found advisable to try condensed milk. Great improvements have been made in methods of condensing. Good condensed milk, says the *Scientific American*, should when poured from a spoon, be glossy, the more glossy the better. It should be ropy or stringy like very heavy syrup.

The color should be that of cream, but the color varies according to the season of the year in which the milk is condensed, the same as milk not condensed varies in color. Milk is more yellow in summer, when cows are on pasture, than in winter, when they are fed on dry hay.

Thickness varies with age. Thickening by age is natural to condensed milk; rapid thickening only proves that the milk is preserved in the best manner, and retains in the highest degree the characteristics of milk in its natural state. The thickest condensed milk, if in sound condition, is the most valuable. There is a degree of thickness, however, that is inconvenient. If condensed milk is so thick that it will not run out when the open can is inverted, it is troublesome to dissolve. If it is not actually hard, very little stirring in the can will render it sufficiently liquid for convenient use.

Condensed milk, if properly done, does not destroy cream globules, but leaves the constituents of milk unaltered and natural. One method, therefore, of determining the relative quality of different samples of condensed milk is to ascertain the amount of butter that can be made from each.

### Dilatation of Cervix for Dysmenorrhœa.

Pond (*Annals of Gynecology and Pediatrics*) considers three classes of dysmenorrhœa according to the etiology.

1. Where the cervix is small and elastic.
2. Where the cervix is long, conical, non-elastic, and cartilaginous.
3. Where there are associated flexures.

In the first variety he recommends the use of a light Palmer dilator, one or more times, without anæsthesia. It should be carried to the full expansion of the blades, and applications made to the canal, or a strip of iodoform gauze introduced. This can be carried out at the office.

For the second condition he recommends the free division of the stricture on two or more sides, from the internal to the external os, with thorough dilatation, and the introduction of a stem to be worn ten to fourteen days or longer, if necessary. Following this the cervix should be dilated once or twice a month to avoid subsequent contraction. Very long cervices require amputation.

In cases of flexion where, at times, it seems impossible to pass the light dilator, the Elliot

repositor should be used, the organ carried into retroflexion, when the dilator can be easily passed beyond the angle of flexure. Should the cervix be dense, a heavier instrument may be used, and if this fail incision and the stem are resorted to.

He reports seven cases illustrative of the application of the treatment in the different conditions, and suggest that dilatation be adapted to the relief of stenosis even in young girls.

### The Management of the Abdominal Incision.

Reed (*American Journal of Obstetrics*, September, 1893), in a paper read before the American Association of Obstetricians and Gynecologists, held in Detroit, June, 1893, referred to the occurrence of suppuration during convalescence, and the subsequent development of ventral hernia. These complications he refers to defective methods in the management of the abdominal incision.

These relate, first, to the preparation of the patient; second, to the formation of the incision; third, to the method of closure; fourth, to the remote or after-treatment of the wound. Defective methods of preparation depend chiefly upon failure to recognize and remove the debris and germ elements from the minute interstices of the integument.

Defective methods in making the incision relate chiefly to failure to recognize the linea alba and to make the incision through it. Defective methods of closure relate chiefly to faulty principles in suturing Defective methods of after-treatment relate chiefly to the application of the tight adhesive strap with pad, firmly compressing the incision. The methods recommended consist in a thorough cleansing of the abdomen by the application of, first, oil, next, ether with some strong alkali, cleansing with clear water, followed by the persistent application for over half an hour preceding the operation of a strong solution of bichloride of mercury. The incision should be made carefully in the median line and through the linea alba. The method of closure recommended is by interrupted suture of silkworm-gut, passed from within outward on both sides entirely through the tissues, but so passed that it enters the peritoneum near the margin of the wound, dips deeply into the median tissue, and is brought out through the integument near the wound margin. By this means all the structures are brought into immediate apposition when the sutures are tightented. They should not be tied tightly and the knot should be on one or the other side of the incision.

The wound should be dressed with aristol or boracic acid, and a bandage carefully applied. When the sutures are removed a firmly-fitting adhesive strap should be applied, which does not exert such pressure as will induce compression of the incision with a subsequent tendency to separation of the internal margin. The advantages of the interrupted suture, as here suggested, consist, first, in the simplicity of application; second, in passing through and anchorage in the muscles; third, the apposition of like tissues to like tissues; fourth, painlessness after operation; fifth, minimum possibility of infection.

## MEDICINE

### Hiccough.

Dr. Carino, of Palermo, found a diagnosis of hereditary syphilis, which in every case has proved correct, on the occurrence of an obstinate hiccough a few hours after birth, lasting from one to three weeks. The hiccough proves obstinate to all the usual remedies, but disappears after the child has been treated with Van Swieten's solution, and the mother has taken large doses of iodide of potash. The author believes that the hiccough depends upon a neuropathic diathesis, to the development of which syphilis contributes.

HIS FIRST CASE.—A young doctor attending his first case of labor was very much frightened when the membranes ruptured and the waters gushed out, and while looking in utter astonishment at the placenta, the husband said:

"Doctor, do you think she will die?"

"Die? Of course she'll die. Don't you see her bladder's busted and her liver dropped out?"—*Hot Springs Medical Journal.*

### Abortive Treatment of Gonorrhœa With Oil of Cinnamon.

J. Chalmers Da Costa urges, first, the thorough cleansing of the urethral canal by injecting or spraying within it the 15-volume solution of hydrogen dioxide, with a caution about permitting it to produce much pain by overdistension. The antiseptic solution is then used, either with the atomizer or by injection. It consists of the oil of cinnamon dissolved in one of the liquid petroleum preparations. The first day the solution is made of one drop to the ounce; the second day, two drops to the ounce; and after that three drops to the ounce.—*Philadelphia Polyclinic.*

### Aural Reflex of Unusual Character Due to Impacted Cerumen.

Dr. Samuel Theobald (Baltimore) related the case of a woman about 42 years of age, the mother of a large family and of a non-nervous temperament, who had suffered for six months with an annoying cough and with spells of inability to swallow food. These symptoms increased in severity, and it was noticed that any manipulation of the right ear brought on the attack. A plug of cerumen, which probably had been forced down upon the tympanic membrane by unsuccessful attempts to remove it, was discovered in the right ear. It was removed by syringing, and all the unpleasant symptoms at once disappeared. Ear-cough is, of course, of not infrequent occurrence, but spells of inability to swallow, due to reflex aural irrita-

tion, are rare. Burnett, in his work upon the ear, states that both Senac and Jissot have described cases of this character.—*Journal of Laryngology*, etc.

### Prolapsed Hemorrhoids.

It may be some satisfaction to the doctor, as well as a great comfort to the patient, to know a comparatively easy method of effecting reduction. This is it: Posture may be important, but the best one is not always required. In moderately severe cases the patient may be on his back with knees drawn up. If the hemorrhoids are very tender from strangulation and manipulation, cocaine should be applied till analgesia is fairly well established. Then the part should be thoroughly lubricated with vaseline, and the tips of three or four fingers of each hand applied to the purple projections. Steady pressure is to be applied, while the patient is ordered to press down as in the defecation of hardened feces. Instinctively, and almost invariably he shrinks and draws away from the pressure on the painful swellings, at the same time puckering the already too contracted anal orifice. But when he is made to comprehend that puckering renders reduction impossible, while resolute and persistent straining down relaxes and opens the orifice and allows the swellings to be forced back into the rectum, often semi-instantaneously, he will govern himself accordingly. Sometimes the performance can be terminated more speedily by having the patient assume a squatting posture, after the preliminaries have been attended to. Then the straining down seems to be more thorough and efficient, and the piles, liberated from constriction, slide homeward with little compulsion.

This is the facile reduction of prolapsed hemorrhoids; and the patient can be taught to accomplish it early and easily without the aid of a physician.—*Ex.*

## SURGERY.

### Pepsin in Surgery.

So many and so brilliant have been the exploits of modern operative surgery that therapeutic agents often of equal importance, though less attractive to the ambitious surgeon, have been greatly overshadowed. It is to awaken the interest of surgeons in this direction that I call attention to the wonderful effect of pepsin as applied to diseased skin or mucous surfaces, and also to the arrest of neoplastic growth, by its dialytic action, though a remarkable elective affinity, being able to attack *formed material* and substances of low vital resistance without doing violence to the surrounding physiological conditions.

My attention was first directed to this in mounting tissues for the microscope, when, if the higher powers were used, there was always more or less interference with the cellular definition, owing to the presence of certain products of retrograde metamorphosis which could not be removed without material chemical injury to the tissue under observation. It was, of course, clear that any agent capable of producing the desired result without change in the normal morphological characteristics of the tissue must accomplish it by dialytic action. This, I found could be practically accomplished by strong, active preparations of pepsin, which completely cleared off the debris of cellular activity without interfering with the structural elements under investigation. However valuable a discovery this was from a histological point of view, there remained to be developed a higher effect, which was destined to place this agent in the foremost rank of surgical therapeutics.

The action of pepsin upon indolent ulcers is too well established and recognized to require any discussion in this connection, but there is an application of this agent which commands the highest attention of surgeons —I refer to its effect upon neoplasms, and mucous lesions of specific character. It is in gonorrhœa, gleet and stricture, that its most decided effects are manifested. There is no disease but gonorrhœa in which the anatomical and physiological relations present just such indications as are fulfilled by the dialytic effect of this ferment. Most of the agents which have a direct currative effect upon a gonorrhœal mucus surface will also excite undue inflammation in the structural element of the physiological tissue, and we are forced to forego entirely their therapeutic use. Most of the unfortunate sequelæ to gonorrhœa owe their origin to the use of remedies that, while they may arrest or destroy the specific morbific agent, leave the normal tissues in a worse condition than would have been the result of the disease itself.

But in Pepsin we have an agent which in its digestive or dialytic action removes everything before it until it comes directly to the cellular structure of the physiological tissue, which, however, from every cell-wall, as it were, cries out, defiantly: "Thus far shalt thou go, and no further." With perfect impunity we can saturate a diseased mucous surface with a solution of pepsin, and remove not only the debris of morbific action; but where, the vital resistance is weakened, as is always the case in inflammation, the cellular activity of the disease itself will be attacked without in the least interferring with physiological conditions—for elective affinity is as unerring as polar attraction.

Of course there is some little difficulty in preparing the pepsin in a remidial way, but the formula which I here give to the profession is the one which will be used in putting up the remedy in a large scale for immediate use of the physician. The formula has been tested thoroughly under every possible condition, with most decided and satisfactory results.

I shall be pleased to give any information to those interested in this matter, if they address me personally at Waukesha, where I am carrying on my investigations with this agent, and I hope soon to be able to give the profession some further developments of which I am now satisfied, but which require further corroboration before offering them to the profession as established facts.

FORMULA OF INJECTION.

℞ Pepsin (pure).....3iic
Ac. boracici.....gr. xx.
Infus. vaccin. macro.....ʒ j (cranberries)
Aq. dest.....ʒ iiij.

M. S. Inject every three hours.

I have given the name of *Gonopepsin* to the above for convenience sake.

## GYNECOLOGY.

### Trendelenburg's Posture.

Dr. H. C. Coe, in the *New York Polyclinic*, calls attention to the danger of secondary hemorrhage following laparotomy with patient in this position. The elevation of the hips determinates the blood toward upper portions of the trunk and oozing from small vessels in broken adhesions does not take place until the patient is again placed in the dorsal position. He cites two cases of celiotomy in which the patients came near bleeding to death from this accident. The abdomen had to be again opened and after much difficulty the hemorrhage was checked It can well be seen that even many small arteries may not bleed while in this position, but when the patient is again returned to the dorsal position much blood may be lost. Aside from this objection the fact that the respiration is seriously impaired by the weight of abdominal viscera on the diaphrgam is another serious objection to the posture. I is true, however, the surgeon has a view of the pelvic viscera with the patient in this position that can not be obtained otherwise, and that the intestines do not get out of the abdomen with the same facility as with the patient in the dorsal posture, but in our judgment this advantage is far outweighed by the dangers cited above.

## ARMY AND NAVY.

U. S. ARMY FROM FEBRUARY 11, 1894, TO FEBRUARY 17, 1894.

A Board of Medical Officers to consist of Colonel Charles H. Allen, Assistant Surgeon, General-Lieutenant Colonel William H. Forwood, Deputy Surgeon General Major Charles Smart, Surgeon; Major Walter Reed, Surgeon.

Capt. James C. Merrill, Assistant Surgeon, is constituted to meet at the Army Medical Museum Building, in this city, on the 12th day of March, 1894, at 10 o'clock A. M., for the examination of candidates for admission to the Medical Corps of the Army.

## NEWS AND MISCELLANY.

### A New Way to Execute Criminals.

A bill has been introduced in the Legislature of Ohio opposing hanging and providing that all murderers sentenced to death shall be put out of the way by means of anesthetics which are to be administered under the supervision of a board of physicians and scientists. The condemned man having been placed in a painless sleep, the scientists are to be permitted to take the top of his skull off and watch the actions of the brain and lay bare his heart and other organs and study life there.

The author of the bill is a physician and argues that its passage would give scientists an opportunity to study the currents of life as they have never been studied before, and would undoubtedly result in the most wonderful discoveries to the benefit of humanity.

### State Medical Examiners.

Governor Pattison appointed the following State Medical Examiners under the act of May 18, 1893, the three schools of medicine being represented.

Allopathic—H. G. McCormick, Williamsport, three years; Henry Beates, Jr., Philadelphia, three years; W. J. R. Kline, Greensburg, three years; A. H. Hulshizer, Philadelphia, two years; N. S. Porter, Pittsburg, two years; J. E. Silliman, Erie, one year; Samuel W. Latta, Philadelphia, one year.

Homœopathic—C. S. Middleton, Philadelphia, three years; Hugh Piteairn, Harrisburg, three years; Isaac G. Smedley, Philadelphia, three years; Edward Cranch, Erie, two years; C. F. Bingamen, Pittsburg, two years; Augustus Korndoerfer, Philadelphia, one year; J. F. Cooper, Allegheny, one year.

Eclectic—H. Yeagley, Lancaster, three years; Augustus Niles, Wellsboro, three years; L. B. Oneale, Mechanicsburg, three years; H. B. Piper, Tyrone, two years; J. R. Borland, Franklin, two years; W. H. Blake, Philadelphia, one year; A. B. Woodward, Tunkhannock, one year.

The act also establishes a Medical Council, consisting of the lieutenant-governor, attorney-general, secretary of internal affairs, superintendent of public instruction, president of the State Board of Health, Presidents of the three boards of examiners appointed to-day. The members of the council receive no salary, except the secretary and treasurer, who will receive not over $500. The council will meet twice a year, and supervise the examinations of the State boards and issue licenses to practice medicine and surgery. The expenses of the Board of Examiners, it is provided, shall be paid from fees, and if any surplus above expenses shall remain at the end of any year, it shall be apportioned among the examiners pro rata, according to the number of candidates examined by each. The first meeting of the Examining Boards will be held on the first Tuesday of April.—*Public Ledger.*

### The Approaching Cholera Conference at Paris.

THE EXTINCTION OF CHOLERA.

M. Hanotaux, Minister Plenipotentiary Director of the Consulates of France, and

delegate of France at the forthcoming International Cholera Conference at Paris, has stated to a representative of the French press, in a published interview, the precise object and anticipated results of this Conference. The Conference, he states, will occupy itself with tracking the cholera to its seat of origin—that is, Asia and India, dealing especially with the Meccan pilgrimage; the principal question laid before the Conference is to find thus "the examination of the Asiatic origin of cholera, and the measures to be taken relating to the defence of Europe against this scourge." Without prejudicing the results, M. Hanotaux has reason to hope that this Sultan and the Czar of Persia will assist in arresting the development of cholera at its Asiatic ports of entry and posts of reinforcement. "The English," he observed, "are especially interested, since they hold both ends of the inlet. and outlet, India and Egypt." M. Hanotaux continues as follows: "The Conference builds largely upon the assistance of Great Britain, for one of the most brilliant European hygienists, Mr. Ernest Hart, has denounced Mecca as a main centre, from which European cholera spreads, in an address of widespread influence. He has pointed out that Hagar's well, where the Mussulman pilgrims wash and drink, is nothing better than sewer water; in one day (June 26, 1893) there were 500 deaths at Mecca from drinking this water. Let the pilgrims die for the glory of Mahommed, that is their affair, but they spread the cholera to the rest of the world, and they must be prevented from making us that present. The Paris Conference will mainly occupy itself with this object; it will not be far from agreeing with the English sanitarian, Mr. Ernest Hart, in saying that the extinction of epidemic cholera in Europe may be secured without great difficulty. There are two ways of attaining this result; to ensure everywhere perfectly pure drinking water, and meantime put an end to the cause of insalubrity of Meccan pilgrims. It will agree with him that 'outside of this all measures are illusionarv; fumigations, railway and frontier quarantine, powderings and antiseptic fluids, are only vain ceremonies, simple sacrifices to popular ignorance, the idolatrous homage which dirt pays to cleanliness. The prime focus of cholera is India; its gates of invasion are the Indian fairs and the Meccan pilgrimage. Mecca is the reinforcing station of cholera between the Gulf of Bengal and Europe; it is there especially that the chief danger lies.''

The measures, therefore, wich the International Conference on Cholera at Paris will be called upon to resolve are, M. Hanotaux announces, those indicated by Mr. Ernest Hart in his address at Edinburgh and in America. "Thus we shall undoubtedly instal medical posts and posts of inspection at two points, which he points out as the most important to be watched—Thor and Camaran. Every ship and every caravan of pilgrims will be accompained by a medical staff furnished with all that is necessaay for the purification and disinfection of the sick. The conference will consider resolutions as to the necessary reorganization of the sanitary service of India, the regulations of the great fairs of that country, the organization (as suggested by Mr. Hart) of a system of inspection of the pilgrims before leaving the Indian ports, and the curatorship of the sacred wells in which the Mussulmans bath and drink at the same time." To carry out this, M. Hanotaux concluded, "will be to win a decisive victory over cholera; such a battle is well worth waging."

The following are the delegates for the Paris Sanitary Conference, which will take place at Paris: For France, MM. Barrere, Hanotaux, Brouardel, Proust, Monod; for Germany, MM. von Schœn and Mordtmann; for Austria-Hungary, Count Kuefsten, Dr. Hagel, Dr. Karlinskii; for the United States, Drs. E. Shakespeare, Stephen Smith, and Preston Bailhache; for Greece, M. Criesis and M. Vafiader; for Italy, The Marquis Malespina and Dr. Pagliani; for Portugal, M. Navarro; for Sweden and Norway, M. Due; for Turkey, Turkan Bey, Nouri Pasha, Bonkowski Pasha, Dr. Hamdy Bey; for Persia, a delegate nominated by the Minister of the Shah, in Paris; for Egypt, Achmet Choukry-Pasha, M. Mieville and Sedky-Pasha.

### Physicians In Japan.

An ex-attache writes: "Perhaps the most charming manner of compensating physicians for their care and attention is that which is customary among the natives of Japan. Physicians do not charge for their services, but on the contrary, decline to name an amount, and protest against any idea of remuneration. Patients, on their side, are too proud to accept such services free, and send to the physician—not as a fee, but more as a friendly gift or token of gratitude—a sum of money, proportionrte to the means of the giver, with some pieces of silk, bronze, or lacquer-work; the idea being that medical attandance is by far too important and elevated a character to be desecrated by barter for filthy lucre." What a pity that our Western civilization, with all its common place vulgarity and lack of delicacy, will not admit of adoption of such a charming method of intercourse between the medical man and his patients.—*The Medical Age.*

### Lead Pencil in Uterus.

A few miles from Albilene, Texas lives a lady who passed a lead pencil, full length, into her womb, and, unable to extract it, sent for Dr. Blakemore, who, after a digital examination, assured her she must be mistaken. In six or eight weeks the doctor was sent for; found patient with a tender, fluctuating, inguinal swelling on one side; opened the abscess, and lo! a lead pencil, the veritable one which, entering at os uteri, had penetrated the uterine wall, broad ligament, and approached just beneath the surface of the skin, to be liberated by the aid of the scalpel.

The woman made a good recovery.—Dr. L. A. Gizzard in *Medical Brief.*

## THE LEGAL RESPONSIBILITY OF THE AGED.

J. J. CALDWELL, M. D.,* Baltimore, Md.

History is replete with the failings of old age. The exceptions are rare and stand out like meteors.

"There is a senile dementia, and a form of dementia associated with general paralysis. Dementia also has its degrees and its stages of *forgetfulness*, irrationality, incomprehension, and inappetency. A patient suffering from dementia, as he passes from bad to worse, *first* exhibits want of memory, then *loss* of reasoning power, then inability to comprehend, and lastly, an abolition of the common instincts and of *volition*.—p. 50, *Field's Medico-Legal Guide*.

In the progress of this mental disorder the mind usually dwells only on the past, and the thoughts succeed one another without any obvious bond of association.

Delusions, if they do exist, are only temporary and leave no permanent impression, and for anything recent the mind is exceedingly weak. If it occurs as *acute dementia* in *young people*, it is generally incurable. In old men, in whom it most frequently occurs, it is called *senile dementia*, and indicates the breaking down of the mental powers in advance of bodily decay. The person may become oblivious of names and dates."

Prof. Geo. M. Beard, now deceased, the great neurologist and electrician of New York city, and author of an elaborate work on these subjects, has divided a paper read before the Medico-Legal Society of New York, into three heads, viz:

1st. What is the average effect of old age on the mental faculties? In other words, what is the law of the relation of age to work?

2d. To what extent is the average responsibility of men impaired by the change which the mental faculties undergo in old age?

3d. How shall the effects of age on the mental faculties be best brought to the attention of our Courts of Justice?

These questions have been a life-long study with this scientist, who set about making his investigations without fear or prejudice, and in the full hope that the result of his researches would be made available in deciding the condition of the minds of men past the full maturity of life.

Dr. Beard has deduced these general results from his prolonged investigations, viz:

| | | | | | |
|---|---|---|---|---|---|
| The golden decade is | between | 30 | and | 40 |
| The silver | " | " | 40 | " | 50 |
| The iron | " | " | 50 | " | 60 |
| The tin | " | " | 60 | " | 70 |
| The wooden | " | " | 70 | " | 80 |

He found that seventy per cent. of the work of the world is done before the age of 45. Nearly all the great systems of theology, metaphysics and philosophy are the result of work done between 20 and 50 years of age. And this law holds good in animals and plants as well. Horses live about 25 years, but they are at their best from 8 to 14. Dogs live 9 to 10 years, and are best for hunting purposes from 2 to 6 years. Children born of parents

*Neurologist and Expert in Medico-Legal Proceedures, Etc., Etc.

healthy in middle life (from 25 to 40 years), are stronger and smarter than those born of parents either younger or older than these extremes; and the same fact applies to the breeding of other animals, as in horses, dogs, and cattle. The hen has her best laying capacity at her third year. She will lay in an average life-time, say nine years, from 500 to 700 eggs. In her first year only 18 eggs; in her second year about 110; in her third 130, the golden period; her ninth year only 10 eggs, if any. In old men the faculties morally deteriorate as do the physical.

This does not necessarily make an old man a bad citizen in the true sense of the term, as of a neighbor or a harm-producing person; but unless sustained by a higher power, he is apt to give a looser rein to his feelings and expressions, to display irritability, less consideration for the feelings of others, and if he has had any variety of brain trouble, this is apt to reflect on his every act.

The diseases to which the brain is liable through a long course of years, are many. Such as blows, destroying the memory of names, dates, locations and events; a bereavement has destroyed the memory of names alone. Millionaires once known for their liberality have grown stingy in old age. Hemorrhage in the brain and the various disorders within the cranial cavity have suddenly or more gradually made the clever foolish, the patient petulent, the hopeful despondent; have caused men, and women too, to change almost *instantaneously* their religious and their political doctrines. When the intellect is impaired by disease of any kind, or by the decay of *age*, men cannot distinguish the true path as of old, even when they desire to do so.

The changes in the brain from old age much resemble a diseased condition, either like the result of hemorrhage from the giving away of the cerebral arteries, from thrombosis, from hardening of the arterial coats, from meningitis, congestion, from anæmia of the brain substance, from nerve tissue decay, and from softening; and death in aged persons is more frequently a process than a sudden event, the process being one of very gradual, incapacitating decline of the mental faculties. An old man may begin to die ten or fifteen years before the absolute death of his body really occurs; and, like a tree, he may die beginning at the top and going down to the trunk. The decline in the moral faculties in old age may be shown in studying the lives of such men as Demosthenes, Cicero, Sylla, Charles V, Louis XIV, Frederick of Prussia, Napoleon, Voltaire, Dr. Samuel Johnson, Oliver Cromwell, Ruskin, Dean Swift, Milton, Lord Bacon, Webster, and Horace Greely. Old men decline in various faculties, some becoming peevish, others avaricious; some mean, filthy and tyrannical; others quarrelsome, sensual, unjust, revengeful, and ungrateful for past favors and kindness.

The best average barometer of mental force is the MEMORY, and decline or any deterioration in the power of the *memory* is the *advance guard* in old age, which sooner or later invalidates the forces of the brain. Most men show their mental powers in middle life, while their advanced years are the periods when they *apply* and *reap* the harvest of the work executed or planned in their palmy days. Thus Lord Bacon, Swift, Dickens, Ruskin, Thackery, Carlisle, Emerson, Wendell Phillips, Graefe, Pinel, Luther, Nelson, Harvey, Webster, Jenner, Jefferson, and Washington did their best work before old age got the better of them. Sterne said that "At sixty years of age the tenement gets fast out of repair"; and Emerson says, in his *Plea for Old Age*, "We cannot count our years until there is nothing else to count," and added, "We postpone our literary work until we find that our literary talent *was* a youthful effervescence which we have now lost." Dr. Oliver Wendell Holmes says: "New ideas build their nests in young brains, and the whisperings of *new truths* are not caught by those who begin to feel the need of an ear-trumpet."

Gen. Halleck in his work on "Military Science and Art," shows that mainly all the successful campaigns of history have been fought by comparatively young men, men in the prime of life, and that most of the early successes of Napoleon were gained over old and worn out generals."

In the late civil war of the States, the North began with old generals, and failure was the result, and the average of the later generals who finished up that contest was between thirty-five and thirty-nine years. We find the average age of the fifty-six Signers of the Declaration of

Independence was between forty and forty-five years.

Mr. Guernsey, of the New York bar, said: "From twenty-five to forty may be considered the *seed time* of life; that is, the time when knowledge is accumulated, and stored up for future use."

There are three causes of moral decline in advanced life:

First. Is the overtasking and overexercise through adult life of the physical and the intellectual faculties, to say nothing of early sexual abuses.

Second. Diseases of the brain, or of other organs, which react on the brain.

Third. Intellectual decline, or the gradual process by which all living beings decay and die.

The question of legal responsibility comes up in old age:

First. As to cases of crime by aged persons.

Second. Cases of wills, which are disputed on the ground of senile incapacity.

Third. When it is desired to fix the limit, as to term of office, etc.

Fourth. As to cases of priority of invention, etc.

Corruption in business and in political life, and breaches of trust are common among the old, as every day's papers inform us. Offenses which depend upon sexual passion are not infrequently among the aged, for it is well known that in the decline of life many return to the vices of their youth. Even clergymen, old men, have been charged with such irregularities.

*Cases of Wills* contested on the ground of senile incapacity are frequent enough, often giving rise to much trouble and enstrangement among members of the same family; and an evident presumption would often lead to an incapacity to dispose of by will wisely, the accumulated possessions of a life time.

A man in the decline of old age may be irresponsible more or less in one or more directions, while responsible in others. Few men break down all at once merely from decay of powers, but the faculties leave one by one, as one first becomes defective, or softened if of the brain, while the others remain for a while longer fairly healthy. As an army in retreat moves off, some holding their position while other regiments fall back. Thus the wear and tear of an aged person may be rapid, save where money, the touchstone of life, is concerned, for the old man cares rather for the money *in ipso*, than for the good that money can bring. Grudge or personal spite, unnatural enmity against a person, relative or not, often occurs in advanced age, amounting even to more than a disagreeable eccentricity, to almost a disease, and may influence judgement even against those who have been kind and affectionate toward the individual. It is difficult and generally fruitless to endeavor to remove this prejudice.

Then the aged are liable to be deceived by designing persons and have influences exerted over them which in their better day, they would have seen through or have not tolerated. The case of Horace Greeley may be cited as an instance of the irresponsible condition of an old man, he becoming inordinately fond of money as soon as disease invaded his brain, and yet he became insane the last week of his life and his will was disallowed.

When an old man, previously benevolent and wealthy, becomes in dread of the poor-house and begrudges the fuel for his family, the meat on his table, and the clothing for himself and his family, there is reason to suspect very serious cerebral disturbance, which might suffice to incapacitate him for making his will.

An instance may be cited of an aged clergyman, who all his life had been mean and penurious. In his golden decade, in his thirty-fifth year, he had been a minister of the gospel, a noted preacher. Between seventy and eighty he became worse and worse; becoming a geninue nuisance. He lost his memory and his manners; lost his wife; he then married again under the the most absurd circumstances; was then divorced from the wife, and again married. He then went into gross excesses; lost his physical health, which up to that time had been excellent, and finally lost all his money through the treachery of this last wife, who in the end deserted him in his poverty and in his imbecile condition. This man had during all these years made will after will. His friends now took him in charge and treated him as a confirmed imbecile.

Dr. Brigham, of Mass., says that in this country insanity and other forms of brain trouble are three times as prevalent as in

England, and Dr. Winslow, a celebrated expert in insanity, says: "In the incipient stages of cerebral softening, as well as in organic disintegration of the delicate nerve vesicles observed in what is termed progressive, general and cerebral paralysis, ending either in apoplexy or in progressive paresis or in childishness. In such cases the patient often exhibits a debility of the *mind*, of body and of *memory* more *especially long before* the disease of the brain is suspected in regard to the most trifling affairs of his life. He forgets his appointments, or goes to keep them before the appointed time. He is forgetful of the names of his particular friends with whom he has lived in the closest intimacy; he becomes irritable, mislays his book, loses his papers—he sits down to write on some matter of business and his attention being diverted for the moment, he forgets and leaves his letter unfinished."

The *memory* may be considered one of the most delicate tests of the presence of injury or of the progress of natural *mental* decay in the brain. The case is cited of an old man, who could never recollect the names of the inmates of his establishment, recalling *only* the initial letter of each one. He accordingly kept about him a list of their names so as to indicate them.

Old age, wear and tear will, like pressure from a bone on the delicate substance composing the brain, produce more or less complete death of the sentient being for the time. One of the early indications of softening of the brain is seen in the paralysis of the muscles of the face, *i. e.*, the drawing down of the eyelid, and the distortion at the angle of the mouth from paralysis of the corresponding muscles of the other side.

In many instances these irregularities and extravagances are but the premonitory symptoms of softening of the brain, that terrible malady, incurable and which gradually destroys, one by one, the powers of mind and body, and reduces the poor sufferer to a living death. Sensations as of cold, numbness, pain, and of increased warmth at times may all be felt in a perverted state; in some everything touched feels cold; others can bear only the lightest wraps in bed on the coldest nights of winter.

Prof. Simpson, of Edinburgh, knew persons with incipient signs of general *paresis* to complain of their fingers feeling like sausages, cold and fleshy; and it is well known that on the approach of a paroxysm some have had such a feeling about the tips of the fingers as to lead to the habit of biting their nails—and this habit is known to exist in many inmates of insane asylums. The manners in such people are very variable, being different only in that the feeling of numbness and inertia persist and are on the increase all the time with them; while in the adult healthy individual, if this condition comes on at all, it forms a brief attack following generally a recognized cause, and then leaves the party almost, or as well, as before the attack.

It is the opinion of many eminent physicians that there has been a large increase of brain diseases during the present century, and that this increase has occurred in an accelerated ratio in proportion as the strain in commercial and public life of the people has increased, making the struggle for position, for wealth, and even for existence so much more difficult than formerly, when man's ambition was to live simply and to follow the golden rule, thus requiring increasing struggle for the luxuries of life, which finally culminates in cerebral excitement under which the delicately organized brain is forced to yield. Eccentricity is but a name often covering painful afflictions, and any prolonged exaggerated conditions of eccentricity may be said to constitute disease (page 89, work on the Border land of Insanity, by Andrew Wynter, Esq., M. D., of London). Many mental eccentricities are but the *forernuners* of *serious mental* failure. The inability to grasp a stick, the continued numbness of the fingers, the loss of *memory* in small matters, are often indications of serious cerebral disturbance. Dr. Graves, of Dublin, a distinguished physician and writer, cites a case, who could never remember proper names, and Dr. Samuel Johnson, the great English scholar and writer, the author of the beautifully selected passages in Rasselas of the Happy Valley, would attempt in vain to repeat the Lord's prayer in English in his latter days, and yet he could repeat every word of it in Latin.

Dr. Samuel Rogers, the poet, in his later years, showed peculiarities of *memory*,

very like those of persons known to be suffering from disease of the brain; he even forgetting that he had been a poet. This is an uncommon form of loss of memory, for once a poet, a man thinks himself a poet forever. Throughout history from the ancient fathers to our own times, we find like failures for the period of old age. We need only cite the famous John Randolph and that great jurist Samuel Tilden, of New York.

In the bible we read of David and his follies of his old age; of Solomon and his foibles with the fair sex; of the valor to-day, and the cowardice to-morrow of Elijah, in his flight from Mount Carmel; all in the extreme old age; of Moses, the law-giver, who organized the Mosaic Code, finally disappearing and wandering in the mountains lost to memory and to history, so that with all his legal lore he had not the mother wit to keep his bearings, or to leave his final testamentary evidence for future generations.

It has been said in this trial that many cases might be cited in green old age, where great ability and wonderful acumen were maintained even to the day of death. Such cases when seen at all are like angels' visits, few and far between, and "they stand out like meteors in the midnight sky."

Now comes a review of the last great

> "Scene of all
> That attends this strange, eventful history,
> Is second childhood, and *mere* oblivion,—
> Sans teeth, sans eyes, sans taste, sans everything."

And we may add to this doleful picture, sans will, sans memory, and sans care for those who loved him.

See the picture of this poor old man, shrunken; not in his locomotor power alone, but in mind, and failing in his powers of memory, without which the noblest work of the Creator becomes useless, helpless, motionless and reasonless on the tide of life; is at the mercy of the slightest breeze by friend or foe—whichever most caters to his present whims; or like the feather tossed by the stormy waves, it was something once, but wilted and weighted down by the moisture of the sea, it is but a creature of chance. This old man was lame, blind, halt, toothless, and his "voice had fallen in tone from the mighty starboard watch ahoy!" to the childish, feeblest piping and whistling, like the tiny reed; or like the creaking door in his strength, left to rust and droop until no longer with any to care for it, in the end it tilts and falls, carrying danger in its fall. On top of and above all these three-score years and ten, he suffered from the Grippe, that prostrating, debilitating, life-destroying Grippe, which takes its name from the French word "tongs" or "seizings." The French are very *au fait* in their use and application of the proper words. This disease is known to the Italians as "influenza;" to the people of the far south as the "dengue" or break-bone fever, and in England as the "epidemic bronchitis." It is fearful in youth, prostrating to adults and fatal in old age.

In connection with all this disability, lasting many months, this old man attempts to publish his will. Often then he says to his brother and to his elder sister, "Don't you worry; I have *already* provided for you." He thought he had made this provision, no doubt, but on the contrary he *utterly* forgot to mention them. Poor old man! His good intentions took the place of good actions, which he thought performed, until at last he had neither will nor memory, but existed like a plant—simply on the sap that was left and on the light of other days. This honorable jury must forgive him, for he knew not what he did, being irresponsible, and living on the visions, the *ignis fatuus*, of past recollections—merely a creature of habit and repetition.

Thus his constant effort in business was a mere matter of habit and but the shadow remaining of his former good intentions towards those who were justly entitled to his benificence. He did not even recollect the amount of his income, nor did he provide for over one-third of it, and the little he did attempt to will, he divided to those he had foresworn. His *memory* was but a fume, a mist, like the froth on the beer glass—now present like a bubble, and then gone to rise no more.

# PROGRESS OF OTOLOGY.

LAURENCE TURNBULL, M. D, PH. D.,* PHILADELPHIA.

It is sad, but nevertheless true, that there are still some physicians who doubt the advance of our knowledge of the diseases of the ear, nor do they appreciate the great changes in the methods of treatment. And this is not to be wondered at, especially among those graduates and physicians who do not read the medical journals nor the new editions of standard medical works. However, we expect better things of men who are looked up to as authorities; leaders in the profession, who have every means of reading, *if they will*, the recent reports and literature on this special subject. Nevertheless such is the case, for great ignorance still exists to this day, as will be believed when we inform you that a young specialist came the other day to consult us about a patient he was treating. After having given directions and compared notes and mentioned the necessary advice, he continued, "I have great difficulty in having certain measures carried out. My orders as a rule are neglected because a relative of the patient, a well-known and leading physician, insists on urging his advice; which is to the effect, 'that the only successful cure of deafness is, in his opinion, syringing with soap and hot water,' and all other means of cure are of little use."

This occurrence is quoted as an example of most frequent experience. Most of my readers are well aware of the value we place upon the use of warm, antiseptic, alkaline solutions in the removal of impacted cerumen; and we always advise and urge their use rather than the employment of mechanical interference, such as the use of the steel or silver probe, spoon, or curette.

No aural instrument should be employed without an accompanying good light; and better than all, as reflected by the head mirror. It will be well just at this place to state, that impacted cerumen is a more frequent cause of deafness than is usually supposed, for in two hundred and fifty cases of diseases of the ear, there were thirty cases in which impacted cerumen, by pressure on the membrana-tympani, caused middle ear disease and impaired conditions with annoying symptoms; yet there are thousands of individuals who have their ears filled more or less with cerumen, which not pressing on the membrana-tympani permits fair hearing and causes no annoyance. Then again we have an army of patients that have diseases complicated or caused by such disorders as we enumerate: Nasal and turbinated bone congestion and obstruction; adenoid growths; naso-pharyngeal catarrh; hypertrophied and inflammed tonsils; scarlatina and measles; tropical effects; also in a reflex manner the menopause, irritation of the auditory meatus, cardiac disease, gout, uterine disorders, syphilis, rheumatism, pregnancy, "morbus Brightii," pneumonia; as also from alcohol, ozena, decayed teeth, quinine poisoning, gun concussion, exostosis of the meatus, catarrhal changes with closed or narrowed Eustachian tubes, perforation of the membrana-tympani, polypus of the tympanum, and disease in the labyrinth (internal ear).

This list shows the general relation of aural to other disorders, and will give a slight idea of the great importance of a correct diagnosis when attempting to treat this peculiar class of symptoms of so much importance to every diagnostician. It is well to have at hand the means of examining the ear with a good silver ear speculum, cotton holder, ear forceps, and above all a good head mirror of short focus, and bright, clear artificial light of oil, gas, or some form of steady electric light. There are many other important instruments for precision, without the use of which a correct diagnosis cannot be made; yet with a speculum and mirror, physicians could often save their patients long and expensive journeys, and spare their own reputation, by first using them carefully to make a diagnosis.

There is a peculiar disease of the external meatus to which we wish to refer as it will at times deceive the most expert. It is termed "desquamative otitis externa," and on inspection resembles the ordinary impacted cerumen so closely that at first sight one is easily misled.

The following is a brief report of an interesting case:

* Aural Surgeon to Jefferson Medical College Hospital, Philadelphia, Pa.

J. A. T. was brought from the neighborhood of Philadelphia by a friend, who was also a physician, who had been treating him for acute otitis externa (desquamative). The disorder was the result of exposure during a cold night in February, when visiting in the country. The pain complained of was intense and the mental distress was very great, probably for fear of loss of hearing. Our friend had already attended him day and night, and had administered, during the night, two grains of morphine hypodermically, with various local measures which induced but temporary relief. On examination of the right ear, which was quite deaf, the meatus was found swollen and filled up with desquamating macerated epithelium. By aid of the forehead mirror and gaslight, the softened cuticle was removed with the forceps, and the lining membrane of the meatus was so congested in points that it bled at the slightest touch. The membrani-tympani was in the same condition. This was treated locally with hydrochlorate of cocaine ointment, ten per cent. in vaseline. The Eustachian tube was opened with the Politzer air douche, charged with vapor of chloroform. The patient was directed to use internally tincture of aconite, two drops and three drops of tincture of belladonna every hour; also, four grains of sulphate of cinchonidia, with the use of "ungt. hydrag. oxor. flav.," (gr. j to the drachm, and ¼ grain of morphia). This treatment was kept up and in three days all the painful symptoms had disappeared and his hearing was almost restored, without any perforation of the drum membrane or the involvement of the mastoid.

Numerous cases of this class are constantly brought to our notice in the Jefferson College Hospital as well as in private practice, especially during the months of February and March. If the cases are treated continuously they may be promptly relieved. Anodynes, heat and stimulants are all well in their way, but, like pontoon bridges, are only for the emergency which is bridged over with them, and are all to be discarded for the more decided constitutional treatment.

There are also some diseases of the auditory nerve which will be readily understood from the character of the noises in the ear (tinnitus aurium); or as reflex irritation and inflammation from various diseases which cause hemorrhagic inflammation of the cochlea or the labyrinth, particularly in children; primary acute purulent inflammation of the labyrinth resulting from meningitis, much like similar cases caused by syphilitic disease of the labyrinth; traumatism involving the internal ear, later causing atrophy of the labyrinth; changes in the auditory nerve from typhus, scarlet and other fevers, also from variola, diphtheria and mumps. It may also be comprehended how deafness can be an inheritance through a diseased father and mother. Yet the deafness which is charged to this cause is not as frequent as we would be led to suppose by the imperfect statistics of our institutions for the instruction of deaf mutes.

A large number of cases of loss of hearing are developed during the period of childhood when changes in the organs of hearing may occur—the result of colds, dentition, measles, whooping cough, scarlet fever and cerebro-spinal meningitis. The ears are apt to be overlooked in the great anxiety and fight for the life of the child. When the crisis is over then the poor, damaged ear is perhaps examined, only too late and to find the child profoundly deaf. No one can fully appreciate the parents' distress over a deaf child, especially a mute, and but few can understand the importance of hearing both for social intercourse and educational development, until some one near and dear has lost it.

It is an important matter that obstetricians should teach their nurses some knowledge of the anatomy and physiology of the ear, as the deafness of many of the so-called congenital deaf mutes is the result of post-natal changes. The meatus of the new-born babe is often filled with a cheesy matter, or it may be blood in the meatus or the tympanic cavity.

Another cause is from neglect to treat in time catarrhal deafness, the result of cold from teething or exposure. The nurse is often at fault for placing the infant in draughts of cold air, and for allowing water to enter the meatus and macerate the membrane, or lodging where it might cause acute inflammation. Pain and persistent earache is often not relieved until nature takes the reins and perforation of the drum membrane takes place with, it might be, subsequent extension to the internal ear and brain if not promptly cared for.

# COMMUNICATIONS.

## REPORT OF A CASE OF TWO SEPARATE AND DISTINCT UTERI, CENTRALLY SITUATED AND NOT CONNECTED.*

HANNAH T. CROASDALE, M. D.

The patient, aged sixty-three years, mother of three children, was admitted to the Woman's Hospital for treatment for an abdominal tumor.

Twenty years before, she noticed some enlargement of the abdomen, and in five years it reached, she thought, its present dimensions. No discomfort was felt (except from size) until recently, when she experienced pain and pressure symptoms, and the bladder and rectum became very irritable.

The menopause occurred at fifty, and at that time the woman was confined to bed for several weeks, but there was no especial reason given for this, or she forgot just why she was in bed for that length of time.

Her condition on admission was not very good, although no definite trouble could be found except a systolic heart-murmur. Lungs and kidneys were in good condition.

Pelvic examination externally showed a regular enlargement of the abdomen, and there was percussion-dullness from symphysis pubis to umbilicus and almost from crest to crest of the ilia, with a small area of tympany on the left side. The measurements, as noted, are as follows:

From umbilicus to ensiform cartilage, 8½ inches.

From umbilicus to pubic symphysis, 12 inches.

From umbilicus to right anterior superior spinous process of the ilium, 10½ inches.

From umbilicus to left anterior superior spinous process of the ilium, 10½ inches.

On making digital examination *per vaginum* the cervix uteri seemed small, apparently undergone senile atrophy, and it was pushed backward and high in the pelvis, the whole uterus being pushed backward. I thought the fundus looked forward, but the uterine sound did not pass readily, hence its use was not persisted in.

What seemed to be a fluctuating tumor was appreciated *per vaginum* to the right of this uterus and above the brim of the pelvis, and a small, tender mass was felt in the right parametrium. The patient complained of pain and tenderness when touched, especially on the right side.

*Diagnosis:* Fibro-cystic tumor of, probably, the uterus.

After the usual preparation the patient was etherized and the abdominal cavity opened. On opening the peritoneal cavity the omentum was found to be greatly thickened and congested and extensively attached to the tumor beneath it and to the pelvic walls. It was necessary to ligate and cut in many places, and upon pushing the omentum aside the tumor looked pale and felt and looked like a fluctuating mass. A trocar and canula being used, I was surprised that no fluid flowed through the canula.

The incision was now extended in the abdominal wall upward sufficiently to admit of the withdrawal of the mass entire.

A small nodular mass attached to the lower part of the tumor, having the shape and size of the uterus and being furnished with what seemed to be the uterine appendages, was drawn out of the lower end of the wound and was found to be attached by a small cord-like pedicle to the pelvic brim, a little below the crest of the left ilium.

Another body, to all appearances a uterus with its appendages, was found in the pelvic cavity and fixed by the usual attachments, but had been crowded into Douglas' pouch.

The slender pedicle, not larger than a pencil, which tethered the smaller mass to the pelvic wall was ligated and cut.

The tumor being now freed from its attachments, which were omental entirely, was lifted from its bed. This growth must have derived most, if not all of its nourishment from the establishment of the circulation through the omentum, for it had almost severed its attachment from

* Read before the Philadelphia County Medical Society, January 24, 1894.

other structures, and the omental vessels were enormously enlarged.

The abdominal cavity was cleansed and the opening closed with silkworm sutures, the dressings applied, and the patient was put to bed. Reaction was prompt and good. The temperature for the first four days ranged from 99° F. to 100.4° F. It then rose, and on the sixth day reached 102.6°F., and on the ninth day 105.4°F., when she died of sepsis.

The autopsy showed purulent infiltration at various points in the pelvic cavity. There was also found at autopsy a uterus and appendages in a healthy condition and in the proper position.

Sections from this little body, which hung from the large tumor, were sent to two pathologists. One reported the specimen as being that of the structure of a fibro-myoma. The other pronounced it uterine tissue, and some structure resembling the endometrium.

If this is a separate and distinct uterus, and I think it is, it is an unusual case, a unique case.

We know that bodies which are not properly situated are not well organized, and take on disease very readily. This second uterus had developed from its *cervix* a fibro-myoma. As it grew too large for the pelvic cavity and rose above the brim, the little organ was inverted and so hung suspended from it.

It measures from the internal os to the fundus one and one-quarter inches. The length and size of the cervical portion is exaggerated, evidently from the tension upon it, but as it was cut open in the fresh state it showed quite distinctly the arbor vitæ arrangement of the mucous membrane lining the canal, and the lips and cervical canal were quite natural in appearance. The os internum on the left side admits the passage of a small probe, which passes a little distance along the Fallopian tube. On the opposite side the opening would not admit of the passage of the probe. There are two small ovaries which, on being cut open, showed on macroscopic inspection ovarian tissue. No microscopic examination of this tissue has been made. In the cervical canal, just below the internal os, is a small calcareous deposit.

The didelphic uterus we have seen, and these cases are actually two uteri, separated as far as the cervix and including it, and not two bodies more or less divergent, as in the case of the uterus bicornis. Ollivier's specimen of a uterus didelphys, and divided vagina with a distinct cervix uteri looking each into its own vagina, was taken from a woman who had been pregnant five times. Each segment presented the appearance of a complete uterus, seeming to be two unicorn uteri equally developed and apposed without fusion.

It used to be thought that this malformation occurred only in nonviable embryos with deformities of other organs. It has been seen with ectropian of the bladder, with imperforate anus, and other malformations. But an entire organ, far removed from one in the usual location, I have not seen mentioned.

### CALCIFIED CORPORA LUTEA.

Another specimen is this little body which I at first thought was a lithopædion, but, seeing Bland Sutton's note on calcified corpora lutea, find it to correspond very closely with the description of two specimens which had been sent to him at about the same time. He considered them very rare pathological specimens. Dr. Voelcker secured one from an ovary of a woman who died of mammary cancer very widely disseminated, and he supposed the two little nodules in the ovary to be secondary deposits; but cutting into them found them to be concretions. One was encysted and had outwardly the appearance of a mulberry calculus of the bladder, the other was imbedded in the ovarian tissue and was of irregular shape.

When this specimen was fresh it was of a bright-yellow color, very characteristic of a recent corpus luteum. It cut as would wax, perhaps of firmer consistence.

Those specimens which Bland Sutton describes consisted of dense tissue impregnated with lime salts. Mr. W. A. Meredith speaks of examining a patient and distinctly feeling the hard body through the vagina, and it gave rise to the impression that the swelling might be the sac of an ectopic gestation containing fragments of bone.

Dr. Coe, of New York, recently described a similar body under the impression that it was a bony nodule.

Greatest review in the world—Lost sight restored.

# A CASE OF ERYSIPELAS.*

P. GUNTERMANN, M. D., LOUISVILLE, KY.

Since erysipelas is strictly considered a surgical disease, I do not propose to discuss at length what does not seem to properly belong to the domain of the general practitioner, though he may have to deal with it quite as often as the surgeon. Yet, in order to excuse the report of an every-day occurrence, it becomes necessary to at least make a resume of the leading features then my case may seem to be *apropos*.

We know what erysipelas is. It is an infectious disease manifested by more or less dermatitis, inflammation of the mucous surfaces and also of the serous membranes. It is claimed, and I think justly so, that the first requisite is a wound, ever so small, through which the system becomes infected. The infecting agent is the "erysipelas coccus." That it is a disease communicable from one individual to another, from man to beast and *vice versa*. If it bears a close similarity, not to say, relationship, to other dermatites or erythema nodosum, eczema, etc. The positive differentiation is in the presence of the *erysipelas coccus* found in the blood, the tissues, etc., of the patient.

Erysipelas is conventionally classified E. simple, E. migrans, (fugax); E. nodosum, and E. gangrenosum.

The cause of erysipelas then is, first, a wound, and, second, the coccus erysipelas, a bacterium.

The symptoms, as a rule, are pronounced. It is ushered in with chilliness, a chill, or rigor more or less severe and prolonged. Soon fever sets in, and in most cases the temperature runs high and remains so until the disease abates. The skin is hot and dry, the tongue brown, parched and cracked. Often we have delirium and prostration, always if the disease is protracted.

The local signs make their appearance at the site of injury and infection; we have itching, redness, heat, pain and swelling. The intensity of all these depends on the individuality of the patient.

Erysipelas is more severe in old and debilitated people and those who have a peculiar disposition. There are persons who have this predisposition. The intensity also determines by which of the four varieties we will name the case on hand.

The diagnosis is comparatively easy and seldom, I dare say, are mistakes made in this direction.

The prognosis is nearly always favorable except in the pueperal state—very often fatal—and in the feeble and debilitated, or when complicated by other disorders particularly of the kidneys and contents of the cranium. Nephritic troubles are rather frequent complications.

The treatment is general and local. The systemic treatment consists in sustaining, stimulating foods and medicines, and antipyretics and tonics, occasionally anodynes, etc. Locally we use the different antiseptics in their different forms.

Prophylaxis is easy and ought never to be neglected but very strictly carried out. The patient ought to be especially cautioned to prevent relapses.

It may not be amiss to mention that the erysipelas bacterium has been successfully used in bringing on the disease artificially, for the cure of cancerous disease. It is a mooted question whether the cure is the result of nutritive changes or whether the cancer cells are directly destroyed by the new intruder.

The report of the following case shows in my estimation, all phases of erysipelas.

Mrs. P. is sixty-six years old, is thin and of wiry frame. She is the mother of nineteen (consecutive) children. Has always been well until the climacteric period at about forty-nine or fifty years. Since that time she has had 4 or 5 distinct and severe attacks of erysipelas. The last before this one was of exceptional gravity. The disease traveled all over her body and general septic trouble set in, attended and followed by a number of abscesses. Finally she recovered and was quite herself again until the present attack.

Patient in attending to her feet had wounded the big toe of the left foot. A few days later she became aware of the

*Read at a meeting of the Louisville Clinical Society January 2, 1894.

presence of the old enemy. On the 24th, day of November, 1893, a doctor was called who diagnosed erysipelas, prescribed and did not return. I saw patient for the first time on Nov. 28th, and thence almost daily, making my last visit Dec. 31st, 1893.

This was the patient's condition: High fever, temperature 104° to 105° F.; pulse 140; skin dry and harsh; tongue brown and cracked; great irritability and slight wandering; bowels and kidneys acted fairly well; the left foot and leg were enormously swollen, covered with large blisters, the contents of which were saneous, opaque and the surface underneath slightly granular tending to suppuration; a gangrenous patch at the inner malleolus, and the toe nails ready to drop. This part of the patient's anatomy had to bear the brunt of the infection.

From the knee up the disease migrated by daily making new invasions of the healthy skin. Up the thigh, over the back of the neck, down the left arm, up the neck over the hairy scalp and over the face, down the right arm, breast, abdomen and right thigh. So far the new invasion could be called *simple*. In the right leg and foot the swelling became very great, rivaling its companion. The constitutional changes became alarming. However the patient rallied, the local trouble subsided and she is convalescent.

The treatment consisted in liberal stimulation, light, nourishing food, large doses of quinine and tinct. ferric chloride. Locally I used a dry antiseptic powder covered by boric cotton. I always prefer dry applications, in this case, particularly, on account of the extent of the disease and the discharge from the numerous denuded surfaces.

## A COMPLICATED COLLES' FRACTURE.

E. J. KEMPF, M. D., JASPER, IND.

Mr. C. A. brought his seven-year-old girl to my office in January, 1894, accompanied by his wife. They said the little girl, on her way home from school, had fallen from a fence on her hands and had broken one of her arms. It was now two hours since the accident had happened; they had first called upon Dr. S—— but he was not at home.

I found the left arm of the little girl in a very curious shape. There was a green-stick fracture of the ulna near its upper third, and a Colles' fracture of the radius near the epiphyseal line. A good description of it would be a silver-fork deformity with the handle twisted.

The arm was pronated to the extreme, and could not be turned or supinated. The long axis of the arm was decidedly shortened. The ulna being partly broken (green-stick) at its upper third and bent outward, and the radius being broken at the epiphyseal line, it seemed to me as if one fracture wedged the other.

I explained the fractures to the parents of the child, and advised them to call in Dr. Brannock in consultation and to assist in the reduction of the fractures. This the parents would not consent to. I then explained to them the wedging of the two fractures, one by the other, and that I would have to give the child chloroform or ether, and that I thought it more than likely that one doctor would have to bend back the broken ulna, whilst the other doctor made counter-extension and extension in order to reduce the Colles' fracture of the radius. Furthermore, that a Colles' fracture was always a serious one; that it was sometimes followed by deformity and stiffness of the wrist, no matter how carefully it was reduced and treated; that this particular arm was fractured in a peculiar and unusual manner; that I had never seen one just like it, that I had never read of one just like it, and that it was possible that I was mistaken in my diagnosis of the fracture.

The mother was a child of the forest, or backwoods, and a great believer in *Natur'*. She could "not for the world see" why I made such "a great a-do" about the matter, and said, "Why, doctor! can't you fix it up?"

I answered, "What do you mean by that?"

"Why, get some shingles and tie it up. It'll come out all right. She's young, and she'll outgrow it; and if it is a little crooked, that won't hurt. I know my sister had her arm broken years ago, and never had no doctor at all, and it got all right. It's a little crooked, but she can use it and don't mind it. And my neighbor's boy had it's arm broken, and a doctor set it, and it was right crooked; but he don't mind it any more, and he can use it. Fix up the arm, doctor."

I then appealed to the father, but all he had to say was, "I've got nothing to say at all—at all."

So I picked up my hat and went after Dr. Brannock.

The doctor examined the arm and concurred with my diagnosis. He also insisted that the child be given chloroform, so that the fracture could be properly reduced without giving the child too much pain. But the parents were obstinate, and would not agree to the chloroform.

We now made two propositions to the parents. One was, that they go somewhere else to have the child treated; the other, that we reduce the fracture as well as we could, and that if any untoward deformity occurred, that they take the blame.

They eagerly accepted the latter proposition.

Accordingly I clasped the fingers of the child's hand into my fingers and made forcible extension of the wrist, at the same time I pressed the fragment of the broken radius down into the position; whilst Dr. Brannock took hold of the forearm, with his fingers above and below the fractured point of the ulna, and with his thumbs forced the ulna into a straight line. We used considerable force, but we accomplished our purpose quickly. Whether the lower fragment of the Colles' fracture was completely reduced we could not tell, because the limb was now very much swollen and very painful, and the parents would not allow further manipulation.

After reduction of the fracture, we placed the hand in flexion on a Levis' metallic splint, and bandaged up the arm.

In four days the mother brought the child to my office and I found the arm in good condition. I instructed her to come back in a few days again, or sooner if there was much pain or swelling.

The patient never came back, and what the outcome of the matter is I do not know.

*Remarks:* I have given a history of this case just as it occurred, and now I call attention to a few lessons to be derived therefrom.

*First.* There seems to be an idea among non-medical people that to fix up a fracture consists in putting the limb into some apparatus and then bandaging it up. Whilst this is a very important factor in the proper and successful treatment of fractures, the first and most essential point is the *proper reduction of the broken bone.* If the broken bone is not well reduced, deformity is bound to occur.

*Second.* There are some people who believe that if a doctor has once handled a broken limb and bandaged it up, the after-treatment is of no consequence. Case after case could I relate as having occurred in practice, that I never saw after the first handling of the broken limb.

*Third.* There are some people who are insanely afraid of an anæsthetic, just as there are some who have a holy terror against vaccination, against calomel, against quinine, against baths, etc. And if you trace this mania to the root, you will always find it due to the foolish talk of some doctor who had more tongue than brains.

*Fourth.* If a doctor meets with a case of fracture where the patient himself, or those who are in authority over him, refuse to comply implicitly with the suggestions of the doctor, let him at once either refuse to treat the case, or insist on having a consultation with some other responsible surgeon or physician. If then a suit for malpractice does come up, the attending physician will have a witness worth a ton or two of medical expertism.

*Fifth.* Was it my duty to hunt up the case after the patient failed to come to my office or send me word is a question that I could only answer, "Yes, for my own protection" had there not been a consultant at the first visit, who was acquainted with all the circumstances.

---

"Well, what did your wife give you for Christmas?"

"Why, it was a–er let me see, a very fine–ah–dear me! I can't remember just what it is but I know it is very becoming to her.—*Washington Star.*

# A NEW METHOD OF EXAMINING THE KIDNEY, ESPECIALLY FOR STONE.*

CHARLES P. NOBLE, M. D.†

I desire to report a short history of the following case, together with an exploratory operation which I performed to enable me to examine her kidney, including the pelvis of the kidney and perhaps one inch of the ureter.

Mrs. T. S., aged thirty-seven years, mother of three children, enjoyed good health until six years ago. Since that time she has been more or less an invalid, unable to attend to her duties. The prominent points in the history are that she has had three well-marked attacks of hæmaturia accompanied by violent renal colic (so-called) and that, at least twice, she has passed good-sized stones, the last one coming from the left kidney. In addition to this history of violent seizures of renal colic, she has suffered frequently with milder attacks of paroxysmal pain referred to the region of the right groin, the pain being, perhaps, most acute just above the right trochanter major. Recently these attacks have been of daily occurrence, and have been brought on when she was on her feet. She is, usually, but not always, comfortable when in bed, but shortly after any attempts at walking the pain comes on. The sexual organs are normal, with the exception of a trifling tear in the perineum. The urine has been examined many times and has a very uniform composition. Its specific gravity has varied between 1020, 1013 and 1018; it is acid, and contains pus, bladder epithelium, and ureteral epithelium, but none from the pelvis of the kidney. The urine from each kidney has been examined separately—the urine being obtained by means of the ureteral catheter. Examined in this way it has been found that the urine from each kidney is much the same, the pathological elements it contains being somewhat more marked on the right side. This difference, however, was distinctly marked with reference to the two sides. The urine from the left kidney has always flowed through the ureteral catheter freely and regularly; that from the right kidney has not done so. Upon two occasions the ureteral catheter remained in position upward of twenty minutes, and not more than one or two drops of urine flowed out. Upon another occasion, after waiting thirty minutes with the same result, suddenly one hundred and twenty minims poured out.

Taking all the facts of the case into consideration the conclusion seemed fair that there was a stone in the right ureter, and that probably this was in the pelvis of the right kidney. Several attempts were made, both by Dr. Howard A. Kelly and myself, to pass a ureteral sound along the ureter toward the kidney. It was not possible to make the sound reach above the brim of the pelvis. It was therefore proposed that an incision be made in the loin for the purpose of examining the kidney and the upper portion of the ureter from above.

My experience in performing nephrorrhaphy for movable kidney after the technique of Dr. Edebohls, has taught me the facility with which *a movable kidney* can be drawn out through an incision in the loin. So far as I know, no one has ever treated a non-movable kidney in this way. It occurred to me it might be feasible, and that, at all events an attempt judiciously made could hardly be a source of danger.

Accordingly on December 12th, I made the usual incision in the loin down to and through the peri-renal fat, exposing the lower end of the kidney. With the index finger the kidney was then separated from its connective tissue attachments and gradually drawn down into and out through the wound, so that it was entirely outside. It is now a very simple matter to explore the kidney by thumb and finger pressure, and to make certain that it was in a normal condition. It was equally easy to examine the pelvis of the kidney, and to determine that this contained no stone. Perhaps one inch of the ureter also was within reach.

As nothing abnormal could be felt, the kidney was replaced within the abdomen and the incision was sutured in the usual

* Read before Philadelphia County Medical Society, January 24, 1894.

† Surgeon-in-charge of the Kensington Hospital for Women, Philadelphia.

way—buried silkworm-gut sutures being placed in the muscular layer, and superficial silkworm gut sutures in the skin. No unfavorable reaction followed this operation, and so far as the operation itself was concerned the patient made an uninterrupted recovery. Unfortunately the operation had produced no effect whatever on the symptoms, which are the same now as before it was done.

I report the case simply to bring before you this method of examining the kidney. From my experience in this case and in cases of movable kidney, I believe it will be a simple and safe matter in the hands of a skilful surgeon who has had some experience in kidney work, to remove through an incision in the loin all non-suppurating kidneys having approximately the normal size, for the purpose of a careful examination. The procedure is certainly not one of much gravity, and when done under the conditions laid down should have no mortality. Tentatively I would recommend the adoption of this method of exploring the kidney whenever the symptoms point to the presence of stone in the kidney or its pelvis, and when these symptoms are of sufficient gravity to invalid the patient. I feel confident that as compared with the ordinary method of exploring the kidney through the depths of the incision in the loin, the kidney itself being largely or wholly above the level of the ribs, and imperfectly palpated because of its movability, or examined by means of a puncture with an exploring needle, that there can be no question of the superiority of the method proposed and herewith reported.

Upon theoretical grounds this procedure would not be applicable in cases of abscess of the kidney. Under these conditions, supposedly the kidney would be fixed and not easily separated from its connective tissue bed. Moreover, it would be enlarged, and in addition to this there would be the risk of rupturing the pus sac, perhaps inadvertently into the peritoneal cavity.

# TRANSLATIONS.*

## THE INFLUENCE OF INTERSTITIAL INJECTIONS OF SALICYLATE OF MERCURY UPON THE EXCHANGE AND ASSIMILATION OF NITROGENOUS MATERIALS FROM A QUANTITATIVE AND QUALITATIVE STUDY IN SYPHILITICS.

P. Froloff, of Saint Petersburg, (*Le Progrés Medical*, August 12, 1893), remarks that the views of writers upon the influence of mercury upon the metamorphosis of nitrogenous materials in syphilitics are very various. According to Güntz and Liégeois the interchange is increased, while according to Boëck and Hallopeau, mercury has not any influence upon the exchange within the organism and the production of urea. Lépine and Rémond believe, on the contrary, that mercurial frictions dimish the quantity of nitrogenous compounds in the urine. The same view was held by Stepanoff, Vajda and Rambach, whose works were published in 1875–76.

All of the observations, the number of which is insufficient, do not agree with the conditions laid down by Voit, since all the authors quoted, with the exception of Boëck, have studied the exchange without determining the quantity of nitrogen introduced with the food and eliminated with the alvine dejections.

Noticing this diversity of opinion upon a question of so great importance, and the almost universal defect in the studies upon the subject, Froloff has made a study of the assimilation and exchange of nitrogenous materials in syphilitics under the influence of the mercurial treatment. He selected from the other modes of treatment the introduction of mercury into the organism by interstitial injections of the salicylate of mercury in suspension in liquid vaseline. In the course of his work,

* Translated for THE MEDICAL AND SURGICAL REPORTER by the translators W. A. N. Dorland, M. D., M. B. Werner, M. D., and F. H. Pritchard, M. D.

when the greatest part of his experiments were already completed, appeared the thesis of Dr. Jakovleff, "Upon the Metamorphosis of Nitrogenous Substances in Syphilitics during the Primary Eruption." In this, he observed that results almost identical with his, were obtained in patients submitted to the mercurial treatment by entirely diverse methods. A portion of his conclusions were absolutely analogous to the conclusions of the author cited. Jakovleff chose his patients among recent syphilitics during the recent incubation, and at the commencement of the eruption. In three cases the author had observed the patients without treatment; in three cases the patients were submitted to frictions at the onset of the roseola, and finally in one case, daily subcutaneous injections of the bichloride of mercury were employed. Basing his views upon these severe cases observed closely and for some time, the author has arrived at the following conclusions: 1. The exchange of nitrogen in the period of the first eruption considerably increased, notwithstanding that the temperature remains normal. From a qualitative point of view, the exchange falls. 2. The assimilation of nitrogen from the food diminishes in the same period. 3. Under the influence of mercurial frictions the assimilation of nitrogen is notably improved, the exchange diminished and oxidation increased.

Froloff has studied his cases, not only during the period of the primary eruption, but also during the secondaries. The last experiments were undertaken in the hope that in the secondaries the effects of the mercurial medication would be cleaner, and could be more easily differentiated from the effects of the disease itself. In all he had observed, eleven cases, six of which were syphilitic, with the secondary manifestations and the condylomatous period, and five with the early forms of the primary eruptions. Two patients in the first group were submitted to injections of pure liquid vaseline. One of the patients of the second group was also submitted to injections of pure liquid vaseline during the whole duration of the observation. Each experiment had a duration of from twelve to fifteen days, and was composed of four to five periods of three days, without counting the time necessary to cause a state of equilibrium. The patients were held a fixed regimen. Oxidation was made according to the method of Kjeldal. The quantity of nitrogen in the feces and urine was determined daily by the volumetric method in the apparatus of Borodine. Moreover, each day, in the same manner the quantity of nitrogen in the urea and extractives was determined by the method of Lépine and the uric acid according to the method of Haykraft. The presence of mercury in the urine was determined by the method of Votz. The following conclusions were reached: 1. The injection of salicylate of mercury in suspension produced in syphilitics with the relapsing forms, an increase in the exchange; this increase is sometimes very marked; while during the injections of pure vaseline, which of itself seem to have no action, the exchange fell. 2. From the qualitative point of view the exchange was most complete. 3. The assimilation of nitrogen diminished a little in the same patients. 4. It was noticed in the patients with the recent forms, in whom the exchange was greatly increased, that under the influence of the injections, the exchange of nitrogen fell with diminution in the urine of the products of incomplete oxidation, and the assimilation improved. —W.

---

## COCAINE IN OTITIS MEDIA (Acute).

Wolfstein recommends cocaine in middle ear disease. He claims it to be an abortive, a preventive against suppuration, and an anodyne. The modus operandi is as follows: Instil into external meatus five to six drops of a five per cent. solution of hydrochlorate of cocaine. Pain disappears in from ten to fifteen minutes. Repeat if necessary. Two to three days treatment consisting of four to five instillations daily are sufficient to cure. In very severe cases repeat this treatment daily, and if necessary use an eight or ten per cent. solution.—*Allg. Med. Central Ztg.* —M.

---

## PROSTATITIS.

Ullman recommends following:

℞ Ichthyol.....gr. viiss (0.5).
Extr. Belladonna.....gr. ii (0.15).
Butyr. cacao.....3iv (15.0).
Met. ft. suppos. No. x.

Sig.—Use once or twice daily after evacuation of bowel.

—*Memorabilien.* —M.

## SUPPURATION OF OVARIAN CYST AFTER TYPHOID FEVER.

Prof. Werth (Kiel) removed a dermoid cyst which was suppurating. Typhoid bacilli were found in pure culture. The patient had typhoid fever from October to November, 1891, and applied for treatmenton June 2, 1892, to Dr. Werth, on account of abdominal swelling and pain.

On opening the abdomen the cyst wall tore, showing very thin pus, sebaceous matter and short, thin hair. The cystic fluid showed under the microscope few leucocytes and considerable detritus. No bacteriæ were found. The contents of the cyst were introduced into gelatine, showing, after a few days, pure cultures of the bacillus of typhoid fever.—*Deutsche Med. Wochenschrift.* —M.

## TREATMENT OF AMENORRHŒA.

Dr. D. Labbé (Paris) reports three cases treated with the negative pole (cathode) of a constant current. The positive electrode is applied on the lower part of the abdomen in the linea alba. Applications did not exceed 5 minutes at a time. The intensity of the current was never more than 50 milliamperes. Instruments used should be made aseptic and in all cases the operator should convince himself that the uterus is empty.—*Jour. de Médicine de Paris.* —M.

## THERAPEUTICAL SUGGESTIONS FROM FOREIGN JOURNALS.

### CORNUTINE DURING THE PUERPERIUM.

Dr. Krohle (*Il Raccoglitore Medico*, No. 16, 1893) thinks that cornutine, which Kobert holds to be the true active principle of ergot, if administered during the puerperium exerts a favorable influence upon the uterine involution. He uses the following formula:

℞ Cornutine.....3 cgms. (gr. ½).
Potter's clay.....3 gms. (grs. xlv).
Water.
Glycerine, ana..... q. s.
Sufficient for twenty pills. Six pills per diem.

It is indicated after extraction of the placenta and the membranous residua after abortions. In cases of sub-involution, or where the lochia remain a long time sanguinolent in puerperal endometritis, and, finally, after normal labor to hasten restoration to the normal condition. It is, on the contrary, contra-indicated in hemorrhages during pregnancy and, in weak contractions during the period of dilatation and expulsion.

### PHENOCOLL IN MALARIC ENLARGEMENT OF THE SPLEEN.

Prof. Cervello (*Il Raccoglitore Medico* No. 1, 1893) of the University of Palermo, in a monagraph on phenocoll, asserts that he has observed a notable retraction in size, of the malaric spleen in patients under his care. It is peculiar that other observers have not noticed this. Dr. E. Michell, also claims the same results. He employs intra-splenic injections of a saturated solution, and though it was used but a short time, and in only two subjects, a remarkable reduction was observed in a short time. With this reduction there was also an improvement of the local and general symptoms. The number of red-blood corpuscles was increased over one-third.

### FOREIGN BODIES IN THE ŒSOPHAGUS.

Dr. Ott (*Der Aerztliche Praktjker*, No. 48, 1893,) was consulted by a patient, who, eight years previously, had swallowed a piece of glass. A sound was introduced into the œsophagus, and came in contact with a hard body, at a level with the head of the sternum, which was apparently fixed in the anterior wall of the œsophagus. An attempt at extraction with a long and curved forceps did not succeed. He had no other instrument so that he was obliged to improvise the following: He took a new and very compact sponge and cut a piece out, the shape of a nine

pin, one inch and a half in length and three-quarters in breadth at the base. It was then perforated with a trocar, an urethral bougie pushed through this opening, and carefully tied to the sponge. Besides that he fastened a long thread to the sponge in order to be able to withdraw it in case that the bougie should break. The sponge-tipped bougie was then pushed down below the fragment, and in a few minutes the sponge had swollen so that it filled the entire œsophagus. It was then slowly withdrawn and with it the splinter of glass. Hemorrhage was quite severe, but it yielded to swallows of ice water.

---

PHENACETINE IN INTERMITTENT FEVER.

Dr. Bernheim (*Il. Raccoglitore Medico*, No. 12, 1893,) claims that phenacetine is capable, like the sulphate of quinine, of suppressing the attacks of intermittent fever, if only it be administered in the proper doses and at the right time. Its action is manifest after an hour, reaching its maximum in two hours and ceasing in five to six hours. Hence it follows that it is best given from two to three hours before the onset of the attack. A dose of one gram (fifteen grains) is preferably given at first, and in obstinate cases, one-half to one grams (seven-and-a-half to fifteen grains) two hours before. No inconvenient or disagreeable results were observed. The lowest temperature is not obtained until five to seven hours after the administration. It differs from quinine in producing antipyresis of shorter duration. Its influence may extend over twenty-four hours. Therefore, from its transient action, the attack in some cases may only be retracted. He does not regard the sulphate of quinine as a specific in the true sense of the word in malaria, for it does not act as an antiseptic, but as an antipyretic. The other antithermics, given in convenient doses, and at the proper times, also act in the same manner as quinine.

---

NERVOUS ASTHMA.

Dr. B. Schuermayer (*Medicinische Neuigkeiten*, No. 1, 1893) recommends in nervous asthma the use of Lebert's pills, containing arsenic, quinine and atropine for they will act when all other preparations fail. They have often the disadvantage that the atropine is not well tolerated and causes terrific dryness of the throat. The iodide of soda is also praised but it alone soon loses its action. If introduced into Lebert's formula it acts, with all the force of atropine and without its disadvantages. The two formulas are as follows:

℞ Atropine sulphate.....3 cgms (1/24gr)
Arsenious acid .....6 cgms (1 gr)
Quinine muriate..... .....4 gms (3j)
Extr. gentian .....4 gms (3i)
Sufficient for sixty pills. One to four pills per diem.

℞ Iodide of soda.... .....¼ gms (grs. xlv-3j)
Arsenious acid.....6 cgms (1 gr)
Muriate of quinine.....4 gms (3j)
Extract gentian.....3 gms (grs. xlv)
Althæa root.....5 dgms (grs. vijss)
Sufficient for sixty pills. One to six per diem. Three are a moderate dose though it may be increased.

---

DYSPEPTIC VOMITING IN CHILDREN.

Dr. Tordeus (*Il Raccoglitore Medico*, No. 1, 1893) speaks highly of the following mixture in the dyspeptic vomiting of children:

℞ Pure creasote.....2 4 gtts
Distilled water..... 35 gms (3j. 3j)
Syrup of orange peel.....15 gms (3iv)
A teaspoonful every two hours.

---

CONVALLARIA MAJALIS IN HEART AFFECTIONS.

Dr. Constantin (*Il Raccoglitore Medico*, No. 1, 1893) has employed this drug for a long series of years, in diseases of the heart and claims to have obtained excellent results.

It is a tonic to the myocardium and its influence is felt, little by little, so that it reaches its highest point in ten to twelve days, after beginning its administration. Not all its preparations are equally efficacious. Convallarine, convallamarine and the alcoholic extract are absolutely to be rejected as they yield but uncertain results. The watery extract, on the contrary, seems to him to be capable of giving good results. It is constant in its effects, simple in its preparation, two chief reasons for its suggestions in practice. He usually prescribes the following:

Thymol.....1 gm (grs. xv)
Infuse for five minutes in water 200 gms (3jvss)

Then add—

Watery extract of convallaria 10 gms (3ijss)
Syrup of orange peel.....90 gms (3iij)
To be taken in doses of fifty grams (an ounce and a half- a day) for six consecutive days.

---

SWEATY FEET.

Prof. Kaposi (*Medicinische Neuigkeiten*, No. 32, 1893) recommends, in the treatment of sweaty feet, the following:

℞ Naphthol.....5 gms (ʒj ¼)
Glycerine.....10 gms (ʒijss)
Alcohol.....100 gms (ʒiijss)

Wash the feet morning and evening with this mixture and then dust with the following powder:

Powdered naphthol.....2 gms (grs. xxx)
Powdered starch.....180 gms (ʒvj)

Every morning one may dust into the shoes the following powder:

℞ Powdered talc.....40 gms (ʒjss)
Subnitrate of bismuth.....45 gms (ʒjss)
Permanganate of potash.....3 gms (grs. xlv)
Salicylate of soda.....2 gms (grs. xxx)

PSORIASIS.

In the *Medicinische Neuigkeiten*, No. 32, 1893, the following is recommended in psoriasis:

Chrysophanic Acid.....10 gms. (ʒiijss)
Chloroform.....90 gms. (ʒiij)

To be mixed with a solution of ten grams (two-and-a half drachms) of gutta percha, in ninety grams (three ounces) of chloroform.

WHOOPING COUGH.

Dr. J. Roca (*Arcivos de Gineclogia e. Pediatria*, No. 36, 1893) advises the following preparation, in the treatment of whooping cough:

Distilled Eucalyptus Water.....120 gms. (ʒiv.)
Cherry Laurel Water.....3 " (gtts. xiv.)
Hydrate of Chloral.....2 " (grs. xxx.)
Syrup of Belladonna.....25 " (ʒv.)
Syrup of Codeine.....15 " (ʒiv.)

A teaspoonful every three hours.
The patient should remain in the house, and the air disinfected with a 2: 100 solution of carbolic acid.

CHRONIC DYSPEPSIA IN INFANTS.

Dr J. Roca (*Archivos de Ginecologia e Pedriatria*, No. 36, 1893) states that in such cases the object to be gained is an increase in the acidity of the stomach, by means of either hydrochloric or lactic acid. He employs the following formula:

Hydrochloric or Lactic Acid..... 2 gms. (gtts. xxx.)
Water..... 95 " (ʒiij.)
Syrup..... 65 " (ʒijss.)

A teaspoonful twenty minutes after nursing.

Hydrochloric Acid,
Lactic acid..... āā 1 gm. (gtts. xv.)
Water..... 98 " (ʒiij.)
Syrup..... 75 " (ʒijss.)

Dose, the same as the proceeding formula.

If there are positive signs of dilatation of the stomach, washing out the stomach with boiled water is indicated. Even without dilatation it will give good results, especially before administering the acid.

SENILE INFILTRATIONS OF THE CORNEA.

Dr. Bimbacker (*Hospitals Tidende*, No. 20, 1893) communicates two cases of infiltration of the cornea, in elderly patients, which condition is sometimes met with in old subjects. It takes place into Bowman's membrane and, therefore, is covered with epithelium. After cocainization the supervening epithelial layer is removed by means of a camel's hair brush. A slight quantity of a five-per-cent solution of hydrochloric acid is then applied to the infiltration which, being the phosphate of lime disappears. Any remaining acid is neutralized with a solution of soda. In these cases the reaction is unimportant, and the slight obscuration of vision, which may follow vanishes in the course of a few months.

DYSENTERY AND DIARRHŒA.

Dr. Gelpke (*Archivos de Ginecologia Pediatria*, No. 55, 1893) recommends, in dysentery and diarrhœa of whatever origin, the following formula:

Pomegranate Bark,
Simaruba Bark,..... āā, 5gms. (ʒj¼).
Macerate in for twenty hours in,
White brandy,..... 375gms. (ʒxij).

Six to eight teaspoonful in twenty four hours. In children a teaspoonful.

This formula he has found to be an absolutely certain remedy, in the treatment of dysentery and diarrhœa of any origin. Dysentery will yield in four to eight days, even in the most rebellious cases. It is of especial service in infantile and summer diarrhœas.

A DELICATE TEST FOR ALBUMEN IN THE URINE.

Dr. F. Spiegler (*Giornale Speciale di Farmacia*, No. 12, 1893) recommends the following reagent, in testing for albumen, in the urine:

℞ Distilled Water,.....200gms. (ʒvjss).
Sublimate,.....8gms. (ij).
Tartaric Acid,.....4gms. (ʒj).
Cane Sugar.....20gms. (ʒv).

Some of the reagent is poured into a test tube and the urine is added, little by little, after previously being filtered and acidulated, taking care that the two fluids do not mix. If it contain albumen, there appears at the point of contact, a white precipitate at the zone of separation. This reagent will detect one part of albumen in one hundred and fifty parts of urine.

In all the affairs of life, social as well as political, courtesies of a small and trivial character are the ones which strike deepest to the grateful and appreciative heart. —*Henry Clay.*

## EDITORIAL.

### TUBERCULIN AND ITS VALUE IN DIAGNOSING TUBERCULOSIS IN CATTLE.

Although the use of tuberculin is gaining favor among certain physicians in the treatment of tuberculosis, the best use to which this bacterial product is being put appears to be in the diagnosis of tuberculosis in cattle. The ravages of tuberculosis in the human species, its unquestioned contagiousness and the identity of human and bovine tuberculosis, all conspire to a more careful inquiry into the existence of this disease in cattle. Although rapid advances are being made in the treatment of tuberculosis, the only wise and ultimately satisfactory course to be taken in the line of eliminating the disease, is to cut off, as far as possible, the channels through which infection come.

Much stress has already been laid on the isolations and sanitary methods to be followed in caring for tuberculous patients in order that they may not infect others. The growing sentiment in this direction gives hope that the time is near at hand when there will be little danger of the spread of the disease from patients to family or attendants.

The next most serious channel of infection is believed by many sanitarians to be through the use of milk from tuberculous cows, and the meat from tuberculous cattle. As Americans cook their meat more thoroughly than most Europeans, the danger from this source does not appear to be so great for us as some of the European investigators have thought. There is, however, much difference of opinion on this subject.

In the danger attending the use of milk from tuberculous cows there is less opposition. It was demonstrated some years ago that *tubercle bacilli* could pass into the milk, and therewith the scientific proof of the possibility of infection through the use of milk was furnished. Numerous experiments have been made with the milk from tuberculous cows to determine under what circumstances the milk is to be considered dangerous. From these experiments the conclusion has been reached by many in-

vestigators that the milk of cows affected with udder tuberculosis must be considered infectious, since it contains almost invariably—some say always—tubercle bacilli. It has furthermore been clearly shown by a number of illustrations that this milk of tuberculous cows, not suffering from udder indurations, was infected with tubercle bacilli. Thus Bang* found the milk infections in nine out of sixty-three cows without udder disease. Although other investigations could be cited the facts stated are sufficient to call attention to the importance of knowing that the cows from which the milk is obtained are not tubercular.

The discovery of tubercle bacilli in milk, while a possible task, is a very difficult one. The diagnosing of tuberculosis in cows by means of inoculating guinea-pigs, or rabbits with the milk from the suspected animals, has proven to be a very long and often unsatisfactory proceedure. It is also, a well-recognized fact among veterinarians that cows may be sufficiently diseased to render their milk dangerous without exhibiting any physical signs or symptoms by which the disease could be detected. So insidious is this disease in cattle that it is usually well established before the health of the animal is appreciably affected. This renders a test more delicate than heretofore known, imperative, if the herds which furnish our milk supply are to be freed from tuberculous cows. It is in these cases that *tuberculin* is rendering so much service.

The value of tuberculin in diagnosing this disease, can be better understood by referring to actual tests.† M'Fadyean found it satisfactory in thirty-one out of fifty tuberculous (determined by post-mortem examinations) cattle, and in a later‡ test of twenth-three animals, all in an excellent condition, but one thirteen years-old cow, all were found to be tuberculous. Eber § reports positive results in 84.5 per cent. of a large number tested. M'Fadyean adds: "That taking full account of its imperfections, tuberculin is the most valuable means of diagnosis in tuberculosis that we possess. * * * It is probable that by using the tuberculin test twice, with an interval of some days between the injections, the proportion of errors in diagnosis would be very small." These and similar results obtained by other investigators are gratifying, as in the great majority of these cases the disease could not have been diagnosed ante-mortem without its aid. The thorough inspections of farm herds with this test would soon enable the owners to weed out the diseased animals and eliminate much of the danger from this disease to the coming generations, thus conferring a blessing upon the future herds of cattle as well as upon the consumers of the milk.

In recognizing the great importance of making an early diagnosis, the questions are often asked by interested parties, Where can I get the tuberculin? How can the test be made?

It may not be known generally, but it is a fortunate fact, that *Koch tuberculin* can be purchased in New York. It is somewhat expensive, however, although the preparations of it would be comparatively inexpensive if a large quantity could be used.

*Tuberculin* is made from cultures of the tubercle bacillus, and consists of a substance elaborated by the growth of these bacteria. The danger attending the handling of this germ and the consequent preparation of tuberculin by inexperienced bacteriologists or chemists, precludes the practicability of the home preparation of tuberculin, excepting the city or state authorities employ a man for this purpose

*Tedskrift of Veterinare, 1891. Heft, 5.

† *Journal of Comparative Pathology and Therapeutics*, Vol. VI. 1893, p. 120.

‡ Ibid. Vol. VI, (1893) p. 314.

§ Deutsch Zeitchrift f Thiermedicin Bd. XVIII (1892) p. 321.

and provide him with the necessary apparatus. It is hoped, that the Boards of Health will soon provide a laboratory or laboratories where tuberculin can be secured at a slight expense. It is not improbable that the growing demand for this article will soon become sufficiently great to warrant the undertaking of its preparation as a private enterprise. As the strength of each separately prepared lot of tuberculin should be *thoroughly tested* before it is used in diagnosing the disease in questionable animals, it is hoped that the health authorities will supervise its production, that every dram of the substance that goes upon the market or that is used by state inspectors may be efficient. The answer to the first query is, that, at present, the tuberculin can be purchased the same as other medicine.

The method of applying the test is quite simple. The desired quantity (determined by the strength of the tuberculin) is injected beneath the skin of the animal. If the animal has tuberculosis, no matter how slightly affected, the temperature rises from one to five degrees within six to twelve hours. The subject, over which there is much discussion at present, is the cause of error in the temperature reaction. M'Fadyean had nineteen tuberculous animals out of fifty tested, fail to give the reaction, and five others that gave the temperature reaction were found upon post-mortem examination to be tuberculous. He took the temperature of 103° F. as indicating a reactoin, however, which seems to be somewhat arbitrary and it may explain some of the discrepancies in his experiment. Physiologists have found that the temperature of animals varies in the same individual from 1 to 3° F. during the twenty-four hours. In making the test therefore, the temperature of the animals should be taken as often as every two hours for at least twelve hours before the injection and as often after the injection of the tuberculin (after four to six hours) for twelve to eighteen hours. Should the maximum temperature after the injection be higher than the maximum temperature before it, the excess could be considered as a reaction. In M'Fadyean's (l. c.) list of twenty-three animals, all tubercular, the maximum reaction was 4.4° F. over the temperature of the animal before the treatment. The elevation was detected in some animals in four hours after the injection and in others not until twelve hours had elapsed.

In view of the great danger to mankind of tubercular milk, the benefit that will assuredly come to cattle owners by eliminating this disease and all its predispositions from their herds, and the most comforting of all facts that the disease may be detected in its incipient stage by the aid of tuberculin, the hearty coöperation of all men concerned in the elimination of this disease, is most earnestly commended. In this way the good that will come to the human race through Koch's discovery may eventually become greater than it was hoped when tuberculin promised to be a specific. The most important work for sanitarians to accomplish is to *cut off the known channels of infection*, and tuberculosis in cattle is a menace to the health of the people.

# ABSTRACTS.

## THE CAUSES OF SHOULDER PRESENTATION.*

DR. SIGMAR STARK, CINCINNATI.

The author cited two cases of shoulder presentation in the same patient, the first proving uneventful owing to the prematurity of the child, but the second labor was attended with all the difficulty of this malposition. This was terminated by the delivery of a large child which could not be resuscitated.

Among the factors given as the cause of shoulder presentation, is the doctrine of Hippocrates and Aristotle which held sway for many years, that the fœtus sat upright with its back toward the spine of its mother until the seventh month, when it was either suddenly or very gradually rotated so as to assume the opposite position. Playfair considers a number of conditions as predisposing thereto, among them, prematurity of foetus; excess of liquor amnii; undue obliquity of the uterus; low attachment of placenta; irregularity in the shape of the uterine cavity. More common in multipara than in primipara; accidental causes exert most influence, as falls, or undue pressure exerted on the abdomen by badly fitting or tight stays.

Cazeaux and Tarnier add distortions of the superior strait to the above list. Flanging ilii are considered by some as predisposing factors, likewise the wrapping of the funis about the neck of the child, thereby interferring with the descent of the head. Shoulder presentation is also apt to occur in the second born in the case of twins, and is explained by the laxity of the uterine walls which is apt to exist under such circumstances.

I examined this patient twice with the pelvimeter and found the pelvic measurements normal. After version had been performed in the second confinement, the child, though an exceptionally large one, passed through the parturient canal and pelvis very readily, proving that there was no reduction in the size of the pelvic diameter.

I had hoped that the primary deformity of the uterus upon which Wigand and Danyan lay such stress would receive more consideration in the discussion. This observation has received support from such men as Siebold, Naegele, Schroeder and others. Cazeaux and Tarnier are skeptical on this point, however. Subsequent examination of the case presented failed to reveal any evidence of such condition.

* *Abstract of a paper read before the Obstetrical Society of Cincinnati.

### DISCUSSION.

DR. TAYLOR: I think where the malpositions recur in the same patient, it is almost a certain indication of malformation. And George Engleman, who has written more than any other American on prolapsus of the umbilical cord, traces that to malpositions, and that is almost equivalent to saying there is malposition otherwise, because if the head is all right the cord is not likely to be prolapsed, and so I believe deformity at the brim is more likely to be the cause. The others are undoubtedly true causes, as where there is hydrops amnii, or the presence of twins, there is likely to be malposition. I can recall three cases of shoulder presentation of the second child in cases of twins.

DR. STANTON: I have nothing to say upon this subject that will throw any light upon it. Dr. Stark has gone over the reasons now generally given for this presentation. I think, however, all obstetrical writers refer to the fact that transverse presentations are very often associated with pelvic deformities. The other conditions that favor shoulder or trunk presentations the doctor has referred to. One especially is the great enlargement of the uterus from hydrops amnii, which permits the child to lie in a transverse rather than an upright position. The reason for a frequent association of transverse presentations with pelvic deformities I am not able to explain, but I suppose one reason is the greater obliquity of the brim and the greater difficulty for the head to find entrance to the pelvis, giving lodgment to the shoulders. Also, in these women there are usually other deformities; they are short in stature and their abdomens are short. At least, it has been my experience; so far as I have

observed, cases of pelvic deformity usually occcur in persons of very short stature, whose abdomens are short but enlarged transversely. At the last meeting of this society which I attended, I reported a case of induced labor in a woman, who had had several children. I have referred to this case before and will call it to your minds now. The patient was a woman who had had eight children, all of which had presented by the shoulder except one. Seven of them where deliveries between six and a half and seven months.

DR. PALMER: I, too, cannot throw any light upon this question, but I can refer to my own immediate experience. I have no doubt all the conditions assigned in the causation of this trouble of parturition, exist, as mentioned by the different authorities, but, looking over my past experience, I am pretty well convinced that the pelvic deformity, mentioned by the last speaker, is the cause of most cases. In former years I had considerable obstetrical practice. The patients were mostly of German ancestry. I am pretty certain almost all, if not all, the shoulder presentations occurred in German woman who had a narrowing at the conjugate of the pelvic brim, from what I regarded at the time as the rachitic pelvis. It is easy to understand how a contraction at the pelvic brim, in its antero-posterior diameter, may obstruct a descent of the fœtal head into the pelvic cavity. We know there is a tendency for the head to fall into the pelvic cavity in primi-parous women because of the rigid condition of the abdominal walls, if the pelvis is of normal dimensions, when ordinarily in multiparous women it does not do so, because these walls are relaxed. A rachitic malformed pelvis prevents the normal descent of the presenting head, and the adjoining shoulder is forced down and made to present.

## A ZWANK'S PESSARY IMPACTED FOR NINE YEARS AND A HALF, CAUSING RECTO-VAGINAL FISTULA.

Dr. Ernest A. G. Steele reports a case of a woman, æt. 45, who applied at the Cottage Hospital, Plaistow, to have an "instrument" removed from the vagina. She said that ten years previously she had the instrument supplied by the Truss Society for a "falling of the womb." She never went to the Truss Society again, but six months afterwards a friend removed the instrument and replaced it, and it had never been touched since. For five years she has had pain and discharge, and during the last twelve months fæces have occasionally passed per vaginam. On examination, under an anæsthetic, the instrument was found to be a Zwank's metal pessary, which was firmly impacted in the vagina and the handles of which had cut their way into the rectum about one inch above the anus. The pessary was removed with some difficulty and the vagina was irrigated, when it was found that the fistula was about an inch in length. The edges of the fistula, which were much indurated, were pared and brought together with silk sutures. Three weeks afterward the fistula had healed except at its upper part.—*The Lancet*, 1893, p. 1059.

## A CASE OF TRANSPOSED VISCERA.

Dr. Frederic C. Coley reports a case of a boy, 15 years of age, who had frequently suffered from bronchitis, but when free from an attack of that kind had not complained of any shortness of breath on exertion. On examination the heart's impulse was found to be an inch below, and half an inch internal to the right nipple. The area of heart dullness was normal in extent, but transferred to the right side of the sternum. The liver dullness was absent from its usual position, but there was a corresponding dullness on the left side. The patient was unaware of the displacement of the heart until I pointed it out to him. He had suffered from nystagmus from infancy, and nyctalopia had long been complained of, *i. e.*, his sight was perfect in broad daylight, but he was almost blind in twilight or ordinary artificial light. He was rather small for his age, and there was no sign of puberty. He seemed fairly intelligent, but was said to be somewhat backward at school, though not more than was accounted for by his frequent absences on account of attacks of bronchitis.—*The Lancet*, '93, p. 1059.

# SOCIETY REPORTS.

## THE LOUISVILLE CLINICAL SOCIETY.

*January* 2, 1894.

[Stenographically Reported by C. C. Mapes, M. D.]

### PEDICULATED UTERINE FIBROID.

DR. W. H. WATHEN: This tumor is a pediculated uterine fibroid, twenty pounds in weight, which was attached to the fundus of the womb. The woman had suffered with the tumor for fifteen years; it gradually increased in size, and caused serious local disturbances; it had increased more rapidly during the last two years, and was causing so much pain from pressure, loss of flesh, etc., that she insisted upon having it removed. The tumor did not appear to be firmly connected with the uterus, and was diagnosticated as either an ovarian fibroid, or a pediculated fibroid of the uterus. Her urine was examined by the interne at the infirmary and pronounced normal, with the exception of the specific gravity being 1.030. It was examined at night and probably the examination was not reliable. The urine is always examined before I do a laparotomy. The examination is usually made by my chief assistant, Dr. Louis Frank. If there is any trouble with the kidneys I invariably ask the anæsthetist to give chloroform, believing it less injurious in its action upon the kidneys than ether. But if the kidneys are normal I leave the matter entirely with the anæsthetist, and he administers which ever he prefers. In this instance he began the anæsthesia with chloroform, but shortly afterward changed to ether, so that probably five-sixths of the time the patient was under the influence of the anæsthetic, it was by ether. When the abdomen was opened I observed that the tumor was a pediculated uterine fibroid. The omental adhesions, as can be readily seen, were very extensive, and I have never seen omental adhesions so tough. A large portion of the omentum was removed. There was nothing of special interest during the operation, with the exception that just after the adhesions were separated, Dr. Frank with his hand on the abdomen felt the aorta beating very rapidly, and said the woman's pulse was 130. It was normal before the operation. The operation was quickly completed. I examined her twenty minutes afterward and the pulse was 74. I saw her again at 5.30 in the afternoon, two hours after the operation, and at eight o'clock in the evening—pulse 80. She had passed some urine without catheterization. I saw her no more until eight o'clock the next morning, when her temperature was 102° F., pulse 120, urine scanty, passing about an ounce at a time every two hours. There was nothing in the operation that could induce such a condition. I did not suspect trouble with the kidneys, and thought possibly it might be one of those cases with an idiosyncrasy to the toxic effect of iodoform, as a great deal was sprinkled over the wound, though but little could have gotten into it. There was considerable oozing, and a drainage tube was used for seven hours. The iodoform was all removed, but when I returned at noon there was no abatement of the fever, and the pulse was more rapid. The quantity of urine gradually decreased, pulse a little more rapid and during the night ranged from 130 to 140, and the temperature 101° to 103° F. The next morning pulse still 140, urine decreasing in quantity, and after nine o'clock, no urine was passed and there was none in the bladder. There was but little change in the pulse until five o'clock in the afternoon, when it went up to 150 and then varied irregularly from 160 down to 135. She was unconscious until seven o'clock, when the pulse became imperceptible; she passed into a comatose condition about eight o'clock, dying two hours later. She had no convulsions.

There was not a symptom of sepsis; the gas passed freely and the abdomen was flat. The bandage had to be tightened several times, and when she died the abdomen was flatter than immediately after the operation. There was no iodoform poisoning, and nothing to account for the condition except the kidneys. I had the urine examined before her death by Dr. Frank, and append his report:

"*Mrs. D.—urinalysis.*
Amount for 24 hours, not stated.
Specific gravity, 1.030.
Reaction, acid.
Color, reddish brown.
Albumen, ⅛ by volume.
Sugar, none.
Urea, two per cent.
Uric acid and urates, abundant,
Blood, few corpuscles seen in some fields.
Pus cells, very few.
Epithelia, bladder abundant, few vaginal.
Casts, fatty, finely granular, hyaline."

You will observe that the specific gravity was still 1.030. I am convinced that the first

examination was imperfect, and that the woman had, because of pressure of the tumor upon the kidneys, chronic nephritis, and that the ether had acted as an irritant and had brought about a suppression of urine, probably by causing acute hyperæmia.

I report this case because there are not many such cases reported where death has resulted from either chloroform or ether—more frequently of course from ether, although there are some cases reportcd of death caused from suppression of urine from chloroform. I believe that there are more deaths from the effects of ether upon the kidneys than have been reported. Some operators may not feel that such cases are worth reporting; some may not have observed carefully to discover what the trouble was; and some through carelessness may not care anything about reporting them. I make this report to emphasize the significance of carefully examining the urine in all patients where we are going to give ether, and particularly so in abdominal surgery where there is a large cystic tumor, or hard tumor that by pressure upon the kidneys may have caused nephritis. Relatively there are more deaths from ether following operations for fibroid or solid tumors. I have the urine examined in every case to be operated upon, even for curetting the uterus or for a vaginal operation, before the anæsthetic is given, but I will not give ether again until the urine has been examined by a *thoroughly* competent person. While I might have no trouble in many cases, I believe our patients are entitled to this protection.

DISCUSSION

DR. J. W. IRWIN: The case reported by Dr. Wathen is a very remarkable one. I do not care to have anything to say in regard to the surgery or surgical proceedure, but if this was a case of chronic nephritis as the Doctor says, it is very strange indeed that some evidence of nephritis was not present prior to the operation. The specific gravity of the urine following the operation would not correspond in my judgment to a case of chronic nephritis, and neither would hyaline casts, and as there had been no convulsions and no conditions leading to a semi-comatose state, it would be very hard to understand how chronic nephritis could have been in existence, that terminated in death so suddenly after the administration of ether. I do not quite understand how pressure of this tumor upon the kidneys, protected as they are, could have brought about the condition as stated. It is true that tumors may have some influence bringing on disease of the kidneys, but I do not think it is due to the pressure of the tumor. I cannot conceive how a uterine tumor like the one exhibited, could press upon the kidneys, especially a tumor connected with a movable organ like the uterus. The very fact that this patient lived after the operation without going into a comatose condition until she was moribund, and the further fact that examination of the urine showed the specific gravity to be 1.030, with hyaline casts—anyone competent or not might be able to take the specific gravity of urine—leaves this in my mind an open question as to whether chronic nephritis ever existed, or, indeed, any form of nephritis, prior to the operation. It seems to me that the condition which ended in death must have been due to the operation, either to the ether or shock; or it was due to some disturbance produced in the nervous system that brought about the fatal result. The imperfect report of the case hardly admits of discussion. The last urine examined by the chemist seems to throw no light upon the nature of the trouble, and where or when it was obtained from the patient, I do not understand, as "No urine was passed (for thirteen hours before her death) after nine o'clock (A. M.) and there was none in the bladder." It may have been a case of acute nephritis, but this is merely conjecture.

DR. J. A. OUCHTERLONY: The report of the case is defective in one respect, namely, that it does not state what was the character of the casts. A great deal depends upon that. If the casts were of a character that would indicate chronic nephritis, of course, it alters the case. Simple hyperæmia of the kidney does not give rise to a temperature of 103° F.

DR. W. H. WATHEN; The report by Dr. Frank, plainly states, "Fatty, finely granular, hyaline casts." It is usual in cases that have died from ether, where the ether has acted as an irritant upon the kidneys, that there have been no convulsions, and the patients have gone within a few hours of death before entering into a comatose condition. This is true in nearly every case reported. I suggested that probably this patient had acute hyperæmia of the kidneys, the result of ether acting upon either healthy or previously diseased kidneys. There are two forms of renal hyperæmia, one active the other passive. In the active form the arterioles are dilated; in the passive form there is venous dilatation. In the passive form there will, of course, be no fever, but in the active form you may have a temperature ranging from normal to 103° F., with the character of pulse that I have described, and with the same condition, going into coma and death. This is the history of acute hyperæmia of the kidneys in many cases. Dr. Frank's statement, which I file as a part of this report, would indicate that there had been previous trouble in the kidneys; further, that this patient had hyperæmia of the kidneys, because there were blood casts, and other characteristic condi-

tions of hyperæmia. There is one thing certain, the kidneys caused the trouble, and there was no surgical shock after the operation. The pulse went down to 74, and remained under 85 for ten hours after operation, then rose progressively until death. The temperature ranging from 101° F. to 103° F. The kidneys are not protected as Dr. Irwin suggests, from pressure, but may be badly injured by the pressure of a fibroid tumor of the uterus, or any solid, or even cystic tumor in the abdominal cavity.

---

TRACHEOTOMY FOR REMOVAL OF A BUTTON.

DR. W. O. ROBERTS: One week ago last Wednesday I operated upon a case that was referred to me by Dr. Ray. A child thirteen years of age, the Thursday preceding, had a button between her teeth whistling through it, when by some means it was sucked into the throat, and passed down into the air passages. She was brought to the city the following Tuesday. Dr. Ray made an examination and when she would cough the button would come up into the larynx, sometimes almost entirely shutting off breathing. The button could be plainly seen in the larynx, but could not be grasped. The case was referred to me, and I operated at the Norton Infirmary. Drs. McMurtry, Ray and a number of others being present. Just as the child was going under chloroform, she had a coughing spell, then it seemed to me she had ceased breathing. I made a free opening in the trachea, dividing about four rings, then she coughed a number of times and the trachea seemed to be perfectly free. I opened the wound well and looked up into the larynx, and there was the button which was easily and quickly removed by grasping with forceps. I then closed the wound by passing a suture through the integument and tissues down to the trachea, bringing them together excepting a small point at the lower angle, applying the usual dressing. Absolutely no trouble followed the operation, and on Friday afternoon I removed the sutures; the wound seemed to have perfectly healed, and she went home feeling comparatively well, the operation having been performed on the preceding Wednesday. I have heard from the patient since, and there has been no trouble whatever. The button, which I exhibit, you will see is about three-quarters of an inch in length by one-quarter inch in width.

DISCUSSION.

DR. L. S. MCMURTRY: The case had one very instructive point that Dr. Roberts has brought out, which will bear emphasizing. There was marked disturbance of the respiration when the button was forced up into the larynx and lodged there. It would have been very easy to have overlooked it.

DR. A. M. VANCE: I would like to ask if treatment by inversion had been used in the case reported before operation?

DR. W. O. ROBERTS: No.

DR. J. A. OUCHTERLONY: The case reminds me of a very interesting historical fact: Stephenson, the father of Railways, on one occasion swallowed a sovereign, and with the mechanical ingenuity for which he was celebrated, it occurred to him that he might bring the force of gravitation to bear upon his case in a favorable manner; so an inclined plane was constructed by which he had himself inverted, and sure enough the weight of the gold piece caused it to come down, and all of a sudden it was expelled. He remarked that when he heard the jingling of the gold piece upon the floor he thought it the "Sweetest sound he had ever listened to." I no not suppose anything of the kind would have been practicable in this case.

DR. L. S. MCMURTRY: This occurs sometimes: I remember operating once in the case of a boy who had gotten half of a shell-bark hickory nut hull in the trachea, which had been there for a month. I did a tracheotomy; the usual coughing occurred when the wind-pipe was opened. The foreign body did not present, and I put in a tracheotomy tube. On the fourth day the foreign body was expelled through the larynx, coughed up in a fit of coughing. In coughing, of course, the tube was thrown out, and then the foreign body was also expelled. On investigating the literature I found a number of cases reported where it was believed that opening the wind-pipe was beneficial in enabling the patient to throw out the foreign body. I would like to inquire what has been the experience of the members in this direction.

DR. WM. CHEATHAM: I believe it is a very bad method to insert the tube in these cases. In doing this you have done away with the safety of the tracheotomy. If the wound is held open with sutures, the chances are very much better for getting the foreign body out. I am positive that the tube is not indicated in cases of foreign body in the trachea.

DR. J. A. OUCHTERLONY: One danger in laryngotomy and tracheotomy occurs to me in connection with this case: Not many years ago a friend of mine was called in to see a patient who suffered from paroxysmal attacks of difficulty in breathing, and this gentleman made a diagnosis of tumor of the larynx, and suggested the propriety of an operation. I explained the matter to the family, and inasmuch as he was in frequent danger of suffocation every day and his sufferings were intense, they consented. I gave the patient chloroform, and my friend made an incision through the cricoid and trachea and proceeded to insert a tube. In doing so

the patient ceased breathing. The operator ceased momentarily, and again proceeded to insert the tube, and with considerable more effort, when the patient ceased breathing for good. When an autopsy was made it was found that the soft structures lining the trachea had not been pierced by the knife, and when the tube was pushed in the membrane was pushed before it effectually shutting off the patient's wind. No tumor was found.

DR. W. O. ROBERTS: I have not much to say in closing the discussion: I want to mention a case that I operated upon some time ago, and possibly may have mentioned to this Society:—A child had gotten a shoe-button down into the wind-pipe, and every effort was made to get it expelled without operation. Inversion was used several times without effect. Operative interference was finally determined upon, and as the child was going under the anæsthetic, in fact had gotten pretty well under its influence, there was a violent paroxysm of coughing, the child becoming perfectly blue in the face. When this condition had passed off anæsthetic was resumed, and after it was thoroughly anæsthetized the trachea was opened and held open for quite a while, the child was inverted slapped on the back, etc., still no foreign body came out. The wound was then stitched open, and no tube or anything else put in. I saw the child the next day twice, and no foreign body had escaped. On the second day after the operation I visited the patient again, and found that the button had been passed by the bowel. I am satisfied that this child coughed up the button and the relaxing effect of chloroform upon the muscles of the larynx allowed it to come out and it was then swallowed.

I think one cause of failure in operations of this kind is due to the fact that the opening in the trachea is not made large enough; that is, the incision is too small for the foreign body to get out. One of the first operations of the kind I ever did was for the removal of a cockle burr. I opened the trachea but the foreign body was not coughed out. I then put in two hooks to hold the wound open; these hooks were what is known as the "double-hook" and fastened around the neck. The following day the child had a violent paroxysm of coughing, strangling for breath and pulled the hooks out. In a very short time it was dead. I made a *post mortem* examination, and found the foreign body, (cockle-burr) in the larynx, completely closing it. I suppose the child was not able to get any air from the opening in the trachea and suffocated. In that case I believe if the opening in the trachea had been sufficiently large, or had been stitched open, the foreign body would have been coughed out. After the result in that case I determined never to use an instrument of any kind or description again in the trachial wound, but passed two sutures through either lip of it, one above and one below, and tie them around the neck so as to have a good free opening. Since then I have done quite a number of these operations and the patients have all gotten well. One was a very remarkable case in a child at Owensboro, Ky., who had swallowed a tin whistle. I made a free opening in the trachea, and tried every way after the opening was made to have the foreign body expelled. I passed a pair of forceps down into the trachea thinking possibly I might grasp it; but failed. On the third or fourth day the child had a paroxysm of coughing, raised up in bed, and the foreign body flew across the room.

---

Dr. P. Guntermann read the essay of the evening

## A CASE OF ERYSIPELAS.

(See page 312)

### DISCUSSION

DR. WM. CHEATHAM: I do not agree with the essayist that the diagnosis of erysipelis is always very easily made. I have seen a great many cases, where there was an abcess of the tear sac which had been diagnosed as erysipelas. My experience has been that it is quite common for physicians to make diagnosis of erysipelas in abscess of the tear sac, when there is no erysipelas.

DR. C. G. LUCAS: I remember about two years ago I had a case of erysipelas involving the left forearm and part of the arm, and in the treatment I used gauze saturated with 1 to 500 bichloride of mercury. In addition to that I had read somewhere, that where you have erysipelas, particularly of the extremities, by passing an adhesive plaster upon each edge it might be confined. I tried the plaster in this case and found it succeeded very well. It seems to me that some persons are peculiarly susceptible to erysipelas.

DR. A. M. VANCE: I have had a great many cases of erysipelas to treat, and have found that the use of the alimentary canal as a drain to the general system acts as a valuable aid in keeping down the high temperature, also seeming to aid in the rapid cure of the disease; therefore, I have been in the habit of giving salines with considerable regularity. I have always used whiskey internally, and locally I use glycerine and carbolic acid. This applied often, every day, I have found in most cases to arrest the spread of the inflammation, seemingly to absorb it, and keep it within its bounds. I use a small amount of carbolic acid in glycerine, not more than one part in one-hundred, and apply it on antiseptic gauze. It seems that the affinity gly-

cerine has for water deprives the tissue of fluid, and in that way bleaches them, making it a valuable antiphlogistic locally. I believe if there is a specific for erysipelas, we have it in carbolic acid. I do not think I have ever seen a case of erysipelas die, and I have had a great many. In my experience for the last ten years I have noticed how seldom we see erysipelas following wounds that we make. It is an uncommon thing, I believe now, to have a case of erysipelas in wounds made by the surgeon, while years ago such cases were not in infrequent. This is evidently entirely due to the proper cleansing and preparation of the patient beforehand.

DR. J. M. KRIM: I have a number of cases of erysipelas convalescing now. As far as the antipyretic treatment is concerned, I do not believe it does any good. Like Dr. A. M. Vance I think we can get better results by letting the alimentary canal do the work. The administration of salines in my experience has done the most good of any internal medication. As to local treatment, I believe that carbolic acid is the next thing to a specific, although I have had very good results during the last year or two with a preparation called campho-phenic. It is more soothing than carbolic acid alone. The preparation consists of a combination of carbolic acid and camphor. I use with it an equal proportion of liquid alvoline, so as to prevent the too frequent application. Used in these proportions, and applied with a sponge or with anything soft, application will not be necessary more than once every two hours, but with carbolic acid and water it would be necessary to make more frequent applications. It protects the skin and prevents the itching which is characteristic of erysipelatous conditions. Constitutional treatment I do not think amounts to anything as far as superficial erysipelas is concerned. Where there is a phlegmonous condition, of course that requires constitutional treatment; but salines are always indicated.

I want to refer to a couple of cases where the patients had hay fever, and contracting erysipelas it seemed to destroy that condition which had previously existed. I have observed this in two cases that as soon as erysipelas developed there was a disappearance of the hay fever. One case is just convalescing now. I saw him in the first attack two years ago; he was a periodical sufferer with hay fever and was compelled to leave town. After taking erysipelas he had no further trouble with hay fever, and has another attack of erysipelas from which he is just convalescing. I believe that erysipelas may have some effect upon doing away with hay fever.

DR. J. A. OUCHTERLONY: I am very much gratified having listened to my friend Dr. Guntermann's paper; it is exceedingly practical and to the point, and brings up a number of interesting, practical thoughts. In the first place, as to the classification of the disease. Of course we are all aware that there is hardly any disease which presents itself under more numerous aspects than erysipelas. So much so that one is often tempted to ask whether an individual case really is entitled to be considered as erysipelatous in its nature. The variety alluded to by Dr. Guntermann "Erysipelas Fugax," I can hardly believe to be a genuine erysipelas. This variety is described by older dermatologists as "erythema fugax" which comes suddenly and goes as quickly as it came, and while disappearing and as long as it lasts, is lacking in the chief characteristics of an infectious disease. The cause of erysipelas has been considered to be independent of micro-organisms, but I do not think it is. Most recent observations tend to show that it is due to the streptococcus pyogenes aureus. The fatal termination that is so likely to occur in persons of advanced age is also observed in subjects of a very tender age. That is an important practical point. I do not think that in erysipelas occurring in the first two weeks of life the patient ever gets well. At least that is the general impression, and I am sure in my own practice I have never known of a case of infantile erysipelas occurring during the first two weeks, that terminated in recovery.

As to treatment, I am reminded by the remarks of my friend Dr. Vance of a practice that prevailed many years ago in the Demilt Infirmary, New York, introduced by Dr. Sayre. His rule was in cases of erysipelas of the lower extremities, which was the most common seat of the trouble in the laboring class that constitute the patients of that Infirmary, to make a free incision from the knee down to the ankle, and then to administer drastic purgatives. The rule was to make one long, deep incision, then give the patient a dose of calomel; 10 gr. calomel and 20 gr. jalap. The treatment that I have generally adopted has been identical in principle with the saline treatment mentioned by Dr. Vance. I generally use a simple protective with carbolic acid; benzoinated oxide of zinc ointment is a very serviceable preparation in this affection.

It is said that the micro-organisms of erysipelas are found in greatest abundance in the periphery of the erysipelatous area; that in the center there are comparatively few, but at that point where the disease is extending the streptococci are found in greatest abundance. And I suppose it is for that reason that injections at those points have been made of sulpho-carbonate of zinc and other like substance with a view of destroying the septic

agents and preventing the extension of the disease.

DR. W. H. WATHEN: I would like to inquire if any of the members have had experience in treating a case of delivery at term, or premature, in patients suffering with erysipelas, and if so has there been any puerperal trouble following? The same micro-organisms are said to be found in these two conditions.

DR. J. M. KRIM: Four or five months ago I saw a case of erysipelas which was quite extensive, in a patient at about the fifth month of pregnancy. This patient aborted, but there was no puerperal trouble following. I think the abortion was due, however, to the erysipelatous condition.

DR. W. H. WATHEN: I saw in consultation about two years ago, a case of labor where the woman had a severe attack of facial erysipelas, with rapid pulse and high temperature, which caused premature labor at about the eighth month. The attending physician observed every aseptic and antiseptic precaution known in such cases, and the woman had no puerperal trouble whatever, making a prompt and easy recovery.

DR. P. F. BARBOUR: Several references have been made to the antagonism of different micro-organisms: I noticed in a recent issue of the *Therapeutic Gazette*, a report of the case of a young girl who had gonorrhœa and developed erysipelas of the thigh, when it was observed that the gonorrhœal infection immediately subsided, and there was no return of the trouble.

DR. J. M. KRIM: I recently saw a child about six months old that had a discharge from the vagina. Owing to the *pecularities* of the mother, I said nothing about the character of the discharge, nor did I know at first. On the second day I saw the child again, when the discharge was very charateristic and profuse. On the fourth day erysipelas developed, and an examination of the vagina showed that the discharge had almost entirely ceased. However, I instructed that the parts to be douched and on the following day there was no discharge whatever. I hardly think the erysipelatous attack could have stopped the discharge so quickly, but the erysipelas was certainly very well-marked.

DR. P. GUNTERMANN: I agree with Dr. Cheatham that abscesses of the face, particularly about the eye, and swellings coming on from gum-boils or something like that, are very frequently mistaken for erysipelas.

I do not believe that in all cases purgation is the treatment. I think, however, that it is always well to pay close attention to the bowels and kidneys.

As to erysipelas fugax: I simply inserted the word "fugax" in parenthesis in my paper, and did not intend it as a classification.

I believe that a simple dry application is very much better than any wet application, at any rate that has been my experience. Also in a great many cases I have treated, I never succeeded until I perfectly saturated them with an iron preparation. I used tincture of iron *neutralized*, because it makes a fairly pleasant drink diluted with water.

---

### CASE OF RHEUMATISM WITHOUT HISTORY OF TRAUMATISM OR CONSTITUTIONAL TAINT.

DR. J. W. IRWIN: A lady, twenty-eight years of age, is under my care; she is the mother of three children in a perfect healthy state, with good history, no consumption, no scrofula and no syphilis. Evidence of syphilis were absent in the children, also in the husband and in herself. She was taken with an attack of rheumatism affecting the right knee and the right wrist. Pain was very severe, especially in the knee. There was no history of constitutional disease, neither had she been accustomed to hard work or scrubbing. I was called to see the case after it had been treated ten days. There was a great amount of swelling at the knee joint, surrounding the the entire joint—especially about the patella. On the outer side of the patella, parallel with the joint, pain was very intense. I suspected an abscess had formed, and employed exploratory measures which discovered pus. The abscess was opened and discharged I believe about a pint of pus. It is the first case of the kind I have ever seen without any history of traumatism, or the result of constitutional taint. I would like to know if the Fellows have met with such cases, or if such cases are at all common.

#### DISCUSSION.

DR. J. M. KRIM: I saw one case some time ago in a man who had gonnorrhœa, both knee joints being affected. One was not very painful and was not opened. The other was intensely painful; an abscess had formed which was opened and about a half pint of pus evacuated. I believe that it was the result of the gonorrhœal trouble. While this condition of swelling, pain, etc. was going on, there was no discharge from the penis, but after he obtained relief from the rheumatism, the discharge came on again from the penis; it was more modified than it had been originally, but still continued.

---

### ACUTE ŒDEMA OF THE LARYNX—INTUBATION.

DR. WM. CHEATHAM: A man, fifty-nine years old, was brought to my clinic the other day during my absence, and was sent around to my office. He suffered very great difficulty in breathing. I was busy at the office, but as

it was an urgent case I saw him at once and found it to be one of acute œdema of the upper part of the larynx and referred the case to Dr. Dugan who was at that time holding his clinic at the College. There was a very large cicatrix of the pharynx which indicated to me that the patient had had syphilis, which proved true. Dr. Dugan did a tracheotomy to relieve the difficult breathing; after the patient recovered from the anæsthetic he walked home. The second day afterward I went to see him and found his breathing very difficult, although the trachial wound was opened. I had a small tracheotomy tube with me, and inserted it, but it did not seem to afford any relief. I then decided to do an intubation, but there was some danger in this procedure, on account of the œdema; I feared it might overlap the intubation tube and cover the opening. I took the largest size tube use for intubation purposes, and inserted it without any trouble until it came in contact with the tracheotomy tube, when, of course, it would not go any further. I removed the tracheotomy tube and could then see the intubation tube through the wound in the trachea. As it was a very long tube it extended some distance below the trachial wound. The patients has had no trouble in breathing since; the trachial wound has about closed, no sutures were used. I have had to scarify the œdematous part two or three times, and it is gradually decreasing in size under this scarification, inunctions of mercury and iodide of potassium in progressively increasing doses.

At first I was afraid it was not a case for intubation, on account of the œdema of the throat, fearing as I stated before it might overlap the head of the tube and in that way cut off breathing. But it was perfectly successful.

---

EHRLICH'S TEST.

DR. J. A. OUCHTERLONY: We are all quite familiar with the fact that the diagnosis of typhoid fever in the early stages is often a matter of difficulty, and for that reason, anything that tends to enable us to make a positive diagnosis in the early stage of the disease, must be of value. In this connection I wish to call attention of the Society to what doubtless you are all familiar with, namely Ehrlich's Test. It never responds save in typhoid fever and in acute miliary tuberculosis, and in some acute inflammations. Acute miliary tuberculosis is usually easy enough of diagnosis. Inflammatory affections are attended with such very characteristic symptoms and physical signs, that there is no difficulty in recognizing them. But typhoid fever is sometimes obscure in its beginnings. Of late I have made use of the Test in a number of cases, and it so happened that they all developed under such circumstances as to make the diagnosis obscure, and but for this test I would have been unable to make a positive diagnosis until several days later.

The test is as follows:

1. Saturated solution of sulphanilic aicd in a solution of 50 c. c. to 1000 c. c.

2. A ½ per cent. solution of sodium nitrite.

A quantity of urine is placed in a test-tube with an equal quantity of a mixture of solution of the sulphanilic acid 40 c. c. and the sodium nitrite 1 c. c. the whole being thoroughly shaken. One cubic centimeter of aqua ammonia is then allowed to flow gradually down the side of the tube forming a colorless zone above the yellow urine, and at the junction of the two a deep, brownish red ring will be seen, if the reaction is present. With normal urine a lighter brownish ring is produced without a shade of red.

The color of the foam of the mixed urine and reagent and the tint they produce when largely diluted with water, are characteristic, being in both cases of a delicate rose-red if the diazo-reaction be present, but if not, brownish yellow.

It may be present before the rash appears, on the sixth day, and has been found as late as the twenty-second.

---

### Chrysarobin in Psoriasis.

The London correspondent of the *Bulletin of Pharmacy* says: "The dirty and unpleasant character of chrysarobin ointment is well known. The extent to which it stains the clothes frequently causes the patient to object to a thorough treatment with this medicament in psoriasis. Dr. Dale James finds that chrysarobin can be applied with more cleanliness by dissolving 1 part chryarobins in 7 parts of chloroform, and stirring about an equal quantity of soft petroleum into the mass. The preparation is applied to the psoriatic area with a brush."

# CURRENT LITERATURE REVIEWED.

IN CHARGE OF ELLISTON J. MORRIS, M. D.

THE MEDICAL CHRONICLE OF MANCHESTER ENGLAND.

for February contains an article by Dr. Roger Williams on

**Sarcoma of The Breast.**

The author shows that the relative liability of the female breast to sarcomatous growths is much below the average for the body in general; 9.4 per cent. of the body neoplasms being sarcomatous, whereas only 3.9 per cent. of female breast neoplasms are of this nature. The feature, that, more than any other, has arrested his attention in connection with this disease is the great rarity of its occurrence, as compared with cancer.

The great majority of mammary sarcomas arise in the immediate vicinity of the small ducts (adeno-sarcomas); only rarely do they originate elsewhere (pure sarcomas). This is the more remarkable when we recollect the great abundance of fibro-adipose tissue that goes to make up the breast, which elsewhere is such a favorite starting-point for these growths. Moreover, the mammary integument enjoys even more complete exception from sarcoma than it does from carcinoma; with the exception of a few rare cases of keloid, the author knows of hardly any other instances of sarcoma thus arising. These facts seem to indicate that the abnormal post-embryonic developmental changes, whence the disease originates, are the outcome of abnormal functional activity. The matrix tissue of the initial proliferative changes usually is the layer of hyaline substance immediately surrounding the epithelial investment of the small ducts, which has been shown to be a myxomatous modification of the adjacent connective tissue, consisting of a network of flattened, branching, nucleated cells, embedded in hyaline stroma. Owing to the intimate relationship thus subsisting between the glandular and connective tissue elements, both are usually involved in sarcomatous neoplasms of this part.

The author believes that the glandular structures met with under these circumstances are of neoplastic origin, rather than the outcome of mechanical distortion of pre-existing structures, from the fact that they have often been found within intra-cystic growths several inches long. Nevertheless, it seems certain that these grandular structures do not form an essential element of the disease. The term adeno-sarcoma, given by Billroth to growths thus constituted, is however a good one, and it certainly ought to be retained.

In regard to adeno-sarcomas of the breast, the author's observations would lead him to the conclusion that they are of much commoner occurrence than pure sarcomas, in the proportion of about 80 per cent of the former to 20 per cent. of the latter.

With regard to the treatment, the whole breast, together with the tumor and the overlying skin, should be freely removed in every case at the earliest possible date. Unless the tumor is situated altogether on the anterior aspect of the gland, the fibrous sheath of the pectoral miscle should also be removed with it. Simple enucleation of the tumor must be condemned as an unscientific procedure. After extirpation of the diseased part it is a good practice to wash the wound with a strong solution of chloride of zinc (20 to 40 grains to the ounce). In doing this operation care must be taken to completely remove the axillary mammary processes. When enlarged lymph glands are present the axilla should be cleared, just as is done for cancer.

With regard to the after results, recurrences rarely supervene later than four years after the primary operation. Those, therefore, who survive free from return of the disease after this period may be regarded as cured. Recurrent growths, when operated, should be freely excised as soon as noticed. This practice not only prolongs life, but in many cases, after repeated operations, it has at length resulted in radical cure.

The statistical part of the paper is very full and the social state of the cases which have come under the author's observation is carefully noted, as is also the occurrence of pregnancy and the family history in regard to the occurrence of malignancy in any member of the family. The paper will be continued in the next issue of the journal.

Dr. Frederick Cox reports a "Case of Chronic Tympanic Disease with Marked Irritability to Treatment." The case is distinguished from the general run of such cases by the marked intolerance of medical treatment, and the temporary improvement of hearing power which was produced by an acute purulent tympanitis occurring while under observation.

Dr. Graham Steell reports a "Case of Cirrhosis of the Liver Complicated with Ulcerative Endocarditis."

THE CHICAGO MEDICAL RECORDER

for January contains a paper by Dr. Boerne Bettman, entitled

**Subvolution—A New Pterygium Operation.**

During the last six years the author has followed the method advised with good results. The underlying principle of the procedure is to prevent readhesion by placing a mucous surface in contact with a raw one. To do this he turns the triangular flap underneath, which action can best be described by the term subvolution (turning under). In order to carry out this rule he performs the operation in the following manner:

The pterygium is gathered up by the two branches of a fine forceps serrated at the ends. A knife is passed underneath it close to the cornea, and the triangular membrane is dissected off toward the apex. A suture with a needle at each end is passed through the

apex. Both needles are inserted from above downward, thus leaving a loop of thread on its outer surface. The needles are now passed through the base from below outward. The points of puncture being the ends of parallel lines drawn from the punctures in the apex and just far enough back so that when the flap is turned upon itself underneath the base, the role will correspond with the corneo scleral margin.

The two ends of the suture are now firmly tied, which induces a condition similar to gumming the flap of an envelope to its body. The under surface of the pteryglum is brought in contact almost throughout its entire extent, and adheres. A readhesion to the cornea is prevented by the role of mucous membrane at the corneo scleral margin.

The only seeming drawback to this procedure is the temporary unsightly thickening produced by the folding. This, however, disappears in a few days, and after a week or two flattens and settles down to the niveau of the adjacent parts of the eyeball. It adheres to the sclerotic.

The raw surface of the cornea is covered with scar tissue and regenerated epithelium.

No matter how much the base of the pterygium contracts after dissection from the cornea, sufficient allowance can always be made by stitching the apex more or less forward.

The apex may be cut off, or not, depending entirely upon the degree of thickness. It is hardly necessary to state that the eye is bandaged and cleaned daily with a boric solution, and that the thread is removed after two or three days.

The operation is especially indicated in large pterygia. Even in smaller ones, where the growth contracts considerably after having been separated from the cornea, it is followed often by good results.

In these cases adhesions will form, which will draw the turned flaps over the sclerotic up to the corneo scleral margin.

John A. Wesener, Ph. C. discusses

**The Clinical Significance of Peptonuria.**

He regards the subject as of the greatest importance, not only from the standpoint of the medical practitioner at lage, but from that of the surgeon, for it is often difficult to diagnose an abscess of any one of the internal organs and the detection of the presence of peptone in the urine goes far to warrant a diagnosis of this kind, its presence usually indicating that suppurative changes are in progress in some part of the system, the diagnostician having carefully excluded all other known causes. The author gives the following tests for peptone:

*Tests for Peptone.* If the urine contains albumen or mucin, it must first be removed. Albumen is removed as follows: to 50 c. c. of urine, add 10 c. c. of a saturated solution of sodium acetate and then a concentrated solution of ferric chloride, until a deep red color is produced. Potassium hydrate is now added, drop by drop, until neutral, then boil and filter; test a portion of the filtrate for albumen. Apply the acetic acid and potassium ferro cyanide test. If albumen is found, the filtrate must then be treated again with a little sodium acetate and ferric chloride solution, boiled and filtered. This is repeated until the test for albumen given above fails to react. the remaining filtrate, having been allowed to cool is then treated for peptone by adding a few drops of sodium hydrate and two or three drops of cupric sulphate; this gives a purple color if peptone is present and is known as the biuret test. A saturated solution of tannic acid gives a good reaction with peptone, but does not show traces that will be shown by the biuret test, and should any of the iron be left in the filtrate, it will form with tannic acid, the tannate of iron, which would obscure any precipitate formed. The removal of albumen by this method has the advantage of also removing the greater part of the coloring matter from the urine.

Devoto recommends the precipitation of albumen with crystals of ammonium sulphate. This takes more time and, as regards the urine, has no advantage over the method given. If peptone is tested for in the blood or visceral fluids, Devoto's method should be used as the results are more accurate.

Albuminous urine which has decomposed cannot be tested for peptone, as some of the albumen has been converted into peptone, and would give a reaction which would be of no clinical value, even though the albumen has been removed. This also applies to decomposed nonalbuminous urine, since bacteria have an albuminous structure peculiar to themselves which will react unless removed.

Urine containing mucin appreciable with acetic acid must be removed. To 20 c. c. of urine add just enough lead acetate solution to produce a flocculent precipitate, an excess must be avoided; filter and test filtrate for peptone, using the biuret test. A simple method of making a quantitative estimation for peptone is as follows: To 10 c. c. of urine apply the biuret reaction; then dissolve a known quantity of peptone in 10 c. c. of normal urine and apply the biuret test. Repeat the last operation until the colors are identical. Having a known strength of peptone solution for comparison this will give you the amount of peptone in the urine. The author has found this to be satisfactory and simple. Where albumin and mucin are absent the biuret or tannic acid test can be proceeded with without the preliminary steps. The author states that in inflammation and the production of pus from bacterial action, peptone is always present in the urine. The paper includes a brief report of several cases.

Dr. W. K. Jaques discusses

**The Operative Treatment of Diphtheritic Laryngeal Stenosis.**

He argues that the treatment of diphtheria, operative or otherwise should be:

First, to neutralize the poison, and to confine the disease if possible, to the primary seat of inoculation.

Second, to support the vitality of the patient, and prevent the ajoining respiratory

passages from becoming susceptible. That operation and medication should be selected which will best admit of carrying out these principles.

In malignant diphtheria, where the primary seat of inoculation has been in the upper respiratory passages and stenosis is secondary, tracheotomy is the best operation. The reasons for this are:

First, the air enters the respiratory passages below the disease and goes into the lungs pure, making auto-infection less likely.

Second, the pharynx and naso-pharynx can be better cleansed than if an intubation tube is in the throat.

Third, in this class of intubation cases, feeding is very difficult, but in tracheotomy it can be done quite well by passing a catheter through the nose.

Fourth, rest is a most important thing in the treatment of inflammation; and not a small item in favor of tracheotomy is that the diseased parts are at rest.

If intubation is performed upon such a case, even by the most skillful operator, the parts are likely to be lacerated; the tube will cause more or less irritation or coughing; the gasping draws poison-ladened air into the lungs, already made more or less susceptible by the labored respiration, and the condition known as "cut-throat" lung is the result.

A large majority of cases of laryngeal stenosis die from the spreading of the disease downward, and in every case that operation and treatment should be selected which will render this the least likely.

When we have reasons to believe that there is loose membrane in the trachea, tracheotomy is considered by many as safest for the following reasons:

First, during the insertion of the tube in intubation, the membrane may become detached, and be pushed in front of the tube; this danger, however, has been over estimated.

Second, the membrane may become loose, and act as a valve over the end of the tube, allowing the air to enter but not to escape, thus causing the chest to become barrel-shaped.

Stenosis caused by or following scarlet fever is best treated by tracheotomy.

In regard to the tube in tracheotomy, the author prefers the Durham tube on account of its shorter curve and jointed inner tube, which, therefore, has a less tendency to produce ulceration of the posterior wall of the trachea from pressure. The objection to this tube, however, is that it is too large and cumbersome. The author has prevented the backward pressure in the ordinary tubes by putting a rubber diaphragm over the retaining piece and slipping it back as far as the tissues would permit. This grasps the tube firmly, at the same time giving it all the movement required.

Every city should have a diphtheria hospital. This, as well as other contagious diseases, should be placed directly in the care of the health department. Isolation should be demanded, and when people are poor and living in a manner that this is impossible, the sick should be removed to a hospital where they would not be a source of danger to others.

The author concludes his interesting paper with the following brief and convenient summary of the cases suitable for operation:

*Intubation.*

First. Stenosis, from primary laryngeal diphtheria.
Second. Non-membraneous laryngitis.
Third. All cases under two years of age.
Fourth. Stenosis from measles.
Fifth. All cases in which tracheotomy is refused and intubation permitted.

*Tracheotomy.*

First. Secondary stenosis in malignant diphtheria.
Second. When there is membrane in the trachea.
Third. Stenosis in scarlet fever.

Dr. F. E. Waxham contributes "A Plea for the Early Climatic Treatment of Pulmonary Tuberculosis." The author urges that cases to receive the greatest benefit from climatic treatment should be sent early while the disease is in its incipiency. These cases must seek a change of climate as a first resort and not as "a last resort" after other methods of treatment have been tried and failed. As soon as the patient shows signs of tuberculosis he should at once be directed where to find almost certain relief. No delay should be sanctioned or encouraged in the vain hope that other lines of treatment may give relief.

There are two classes that should permanently occupy Southwestern Texas, New Mexico, Arizona, Colorado and Utah, and largely constitute the population, those with incipient tuberculosis, and those predisposed to the disease by heredity.

Dr. D. A. K. Steele presents the "Report of a Case of Cerebral Tumor, Diagnosed by Focal Symptoms, with Operation, Successful Removal of the Tumor."

Examination showed motor paralysis and sensory blunting of the right leg; the right patella tendon reflex was much increased; hearing was much reduced in the right ear; there was no choked disc or optic neuritis; none of the orbital muscles were involved. Speech was slow. A diagnosis of cerebral tumor originating in the leg centre of the cortical area of the left hemisphere of the brain and extending downward and forward to the arm and face centres, was made, and operation advised, after specific treatment was tried without avail.

The remaining paper in this issue is "Induration After Lobar Pneumonia," by Dr. Ludwig Hektoen.

### Apomorphine for Hysteria.

Rossen reports success in cutting short hysterical attacks and in preventing their recurrence by the administration of one-tenth of a grain of apomorphine hypodermically. In the case of a morphine user, the impression was given that the apomorphine was the drug to which she was accustomed; and in consequence the morphine habit was permanently broken up.—*Times and Register.*

### Jaundice Due to Simple Obstruction Successfully Treated by Olive Oil.

Dr. Thos. Olive reports two cases in which symptoms, which had persisted for many months under vigorous medical treatment by himself and others, gradually disappeared under the administration of olive oil. He says: "In the treatment of recurrent hepatic colic I do not claim for olive oil that it dissolves the gallstones, nor do I regard the greenish concretions passed per anum by patients thus treated as softened gallstones. Microscopical and chemical examination have shown them to be practically nothing else than inspissated oil. Nevertheless as to its decided influence for good in certain cases of obstructive jaundice, I have no doubt. In such cases our experience at present is in advance of the therapeutical explanation."—*Lancet.*

### Reducing the Tonsils.

Dr. Tact De Blois believes that galvanocaustic puncture, while not a perfect method is the best we have at present at our command for reducing the size of enlarged tonsils. The operation is performed under cocaine anæsthesia. The cautery point is pushed about a quarter of an inch into the tonsil avoiding the crypts. The pain is not very severe. Slight inflammation follows and a little sloughing from the burned parts. Diminution of size, estimated at about a quarter, occasionally follows at the end of ten days after the first burning. The igni-puncture should be repeated perhaps three times. About half the cases will show some improvement after the first burning. In about quarter of the cases this treatment will prove so slow or so unsatisfactory that resort will have to be had to tonsilotomy.—*Bost. Med. and Surg. Journal.*

### The Action of Permanganate of Potassium in Rendering Morphia Inert.

At a meeting of the Medical and Surgical staff of the West side German Clinic, Forty-second street, New York, Dr. Wm. Moor, one of the physicians to the clinic, recently gave a demonstration on his own person of the efficacy of permanganate of potassium, as an antidote for morphia. Against the earnest protestations of those present, he swallowed 3 grains of sulphate of morphia in solution and immediately afterwards he drank a solution of four grain of permanganate of potassium in four ounces of water. He was carefully watched, but none of the ordinary effects of morphia on the system were observed, and he has since stated that he experienced no ill effect whatever from the poisonous dose taken. He claims that morphia or any of the salts of opium are immediately rendered harmless by contact with the permanganate. The antidote should be administered as promptly as possible after the morphia is taken. Experiments indicate that the permanganate does not control the action of the poison after it is introduced into the general system. Since the demonstration it has been claimed that the honor of discovery is really due to Dr. Wm. Condy, of London.—*Bost. Med. and Surg. Journ.*

### Post Mortem Idrosis.

A writer in the *International Medical Magazine*, records the following curious phenomenon in a case of death from angina pectoris. "The face of the corps seemed to be bathed in prespiration, the moisture reproducing itself after being wiped off, in spite of the presence of rigor mortis, and other unmistakable evidences of death. This most extraordinary phenomenon was witnessed by several local physicians, who also viewed the body. The funeral on that account was delayed several hours, until decomposition had fully set in."

### Burns.

Campho-phenique.....
Olive-oil.....āā ℥ss
M. Rub up the cocaine and campho-phenique and add the olive-oil.

—*Medical Review.*

## SURGERY.

### Intubation of the Larynx in Private Practice—Results in 78 Cases.

C. M. Whitney, in *Bost. Med. and Surg. Journal*, divided according to age. They were:

| | Cases. | Recoveries. |
|---|---|---|
| Under 1 year | 2 | 0 |
| One—2 years | 12 | 3 |
| Two—3 years | 18 | 6 |
| Three—5 years | 20 | 5 |
| Five—10 years | 26 | 12 |
| | 78 | 26 |

This table shows 33 per cent. of recoveries. When there is persistent and increasing retraction of the intercostal, supusternal and super clavicular spaces, no advantage is to be gained by waiting, but intubation should be done at once. The writer mentions some changes he has made in the apparatus and gives careful direction about the details of introducing the tube. A list of the articles of food which may be administered during the wearing of the tube is given. From the fourth to the sixth day the tube should be removed. This is far more difficult than its introduction. An extractor divised by Dr. Nichols, of the Boston City Hospital, is favorably mentioned. Intubation is an operation especially adapted to private practice—always available, can be done early, and is painless and bloodless. It is not advisable when the tonsils are so large that they prevent the necessary manipulation or when the fauces are full of putrid debris and the epiglottis is immovable from the distructive action of the disease.

### The Treatment of Influenza.

Dr. Wm. Henry Thayer writing to the *Medical Record* of his treatment of influenza in the epidemics of 1891 and 1892 says: It was treated as we should treat diphtheria, with bichloride of mercury, adopted on the ground of its being a powerful germicide. I treated all my cases that way and with excellent results. In seven attacks it was given in doses of 1-30 gr. every half hour at the outset for several hours, and continued at longer intervals afterward. The effect was always good on the prime disease, and the convalescence usually so tedious, and in lessening the frequency of secondary affections.

### The Indications For Bleeding.

Sir. Benjamin Ward Richardson, is rather fond of bleeding, and in his *Aesclepiad* he has published several articles describing his experiences and his successes. In the last issue of this Journal he tries to indicate the moment for bleeding, and the conclusions to which he arrives, are these:

One may bleed—

*a.* In acute spasmodic seizures, as in spasms of croup, in colic and in augina with symptoms of oppression from distension of the right side of the heart with blood.

*b.* In acute pain, membranous or spasmodic, as in sudden pleuritic or peritoneal pain, or in pain from passage of a calculus hepatic or renal.

*c.* In acute congestions of vascular organs, as of the lungs or brain, apoplexies.

*d.* In cases of sudden shock or strain, as after a fall or a blow, sunstroke or a lightning shock.

*e.* In some exceptional cases of hemorrhage of an acute kind, unattended by pyrexia.

This, it seems to us makes a rather poor showing for venesection. It means practically, that bleeding is only needed in urœmic convulsions and dangerous apoplexy, for in most of the other conditions morphine, or some heart stimulant would answer as well, if not better.

The fact is, bleeding has gone forever from ordinary therapeutics. This is not because it is useless, but because modern science has devised better things as substitutes. Bleeding was legitimate and effective in its day, and would be useful now if our materia medic had not been so enlarged. We have given it up, not because of a change of fashion, but because we have outgrown it.—*Ed. Medical Reaord.*

## ARMY AND NAVY.

U. S. ARMY FROM FEBRUARY 18, 1894, TO FEBRUARY 24, 1894.

The leave of absence on Surgeon's certificate of disability granted Major Edward B. Moseley, Surgeon, U. S. Army, is extended one month on surgeon's certificate of disability.

First Lieutenant Benjamin L. Ten Eyck, Assistant Surgeon, U. S. Army, will report in person to Colonel Joseph C. Baily, Asst. Surg. General, president of the examination as to his fitness for promotion.

U. S. MARINE HOSPITAL SERVICE FOR THE FOUR WEEKS ENDED FEBRUARY 17, 1894.

Murray, R. D., Surgeon; to proceed to Key West, Fla., for special duty, January 26, 1894.

Bailhache, P. H., Surgeon; granted leave of absence for twenty days, February 2, 1894.

Purviance, George, Surgeon; detailed as Chairman Board of Examiners, February, 12, 1894.

Stoner, G. W., Surgeon; detailed as member Board of Examiners, February 12, 1894.

Carter, H. R., Surgeon; to report at Bureau for temporary duty, February 2, 1894; to proceed to Brunswick, Ga., as Quarantine Inspector, February 6, 1894; detailed as recorder Board of Examiners, February 12, 1894.

White, J. H., Passed Assistant Surgeon; granted leave of absence for seven days, February 17, 1894.

Carrington, P. M., Passed Assistant Surgeon; granted leave of absence for thirty days, February 19, 1894.

Bratton, W. D., Passed Assistant Surgeon; granted leave of absence for thirty days, January 20, 1894.

Pettus, W. J., Passed Assistant Surgeon; granted leave of absence for thirty days, January 30, 1894.

Vaughn, G. T., Passed Assistant Surgeon; to report to the Secretary of the Treasury for special duty, January 26, 1894.

Young, G. B., Assistant Surgeon; ordered to examination for promotion, February 14, 1894.

Stimpson, W. G., Assistant Surgeon; ordered to examination for promotion, February 14, 1894.

Brown, W. B., Assistant Surgeon; ordered to examination for promotion, February 14, 1894.

Rosenau, M. J., Assistant Surgeon; granted leave of absence for thirty days, February 26, 1894.

Cofer, L. E., Assistant Surgeon; to proceed to Mobile, Ala., for duty, January 30, 1894.

Eager, J. M., Assistant Surgeon; granted leave of absence for four days, January 30, 1894.

Blue Rupert, Assistant Surgeon; granted leave of absence for eight days, January 26, 1894.

Norman, Seaton, Assistant Surgeon; ordered to examination for promotion, February 14, 1894.

Prochazka, Emil, Assistant Surgeon; to proceed to New York, N. Y., for duty, January 24, 1894; to proceed to Buffalo, N. Y., for temporary duty, Eebruary 2, 1894.

## NEWS AND MISCELLANY.

### Medical Society of the State of Pennsylvania.

COMMITTEE ON SCIENTIFIC BUSINESS.

Dear Doctor:—At its last meeting the Medical Society of the State of Pennsylvania appointed—under the provisions of a by-law proposed at Harrisburg and adopted at Williamsport—a Committee on Scientific Business, "To secure scientific papers and to provide scientific discussions for each annual meeting, and to co-operate with the Committee of Arrangements and Credentials in arranging the programme." The members of this Committee are Drs. Dulles, of Philadelphia; Gorgas, of Harrisburg; LeMoyne, of Pittsburg; Tyson of Philadelphia; and Towler of Marienville. The object of this change in the law is to have a permanent Committee which, becoming familiar with the subject, shall find it easier to secure good scientific work than is possible for a committee that is appointed new every year.

The Committee on Scientific Business is working in conjunction with the Committee of Arrangements, of which Dr. E E. Montgomery is Chairman, and will co-operate with it in arranging the programme.

The committee hopes that each member of the State Society will aid it in attempting to make the meeting of the Society of greater scientific importance than they have been in the past. To this end the Committee will welcome suggestions from any member of the Society and especially, at this time, offers of contributions to the work of the next meeting, at Gettysburg, May 15 to 18. It is desired that there should be as many brief, concise, practical papers as possible, and it is proposed to have a discussion on Tuberculosis, devoting the morning to "Medical Tuberculosis," and the afternoon to "Surgical Tuberculosis"

Any communication from members of the Society in regard to the work of the Committee will be welcome by it.

Members of the Society desiring to read papers, or to take part in the discussion on Tuberculosis will please notify the Chairman of the Committee.

DR. CHARLES W. DULLES,
4101 Walnut Street, Philadelphia.

### To Those who Read Medical Society Papers.

We have often seen this notice over doors entering manufacturing places: *Keep out, this means you.* So we write this editorial for the members who took part in the last meeting and for those who will engage in the next, and we add this: *Read it, this means you.*

Time your article beforehand. Boil it down until it can be delivered in fifteen minutes. This rule would have seemed at least two hours for debate in the recent meeting.

Confine yourself to manuscript strictly—interpolations and after remarks are wasteful and exceedingly tiresome.

Be familiar with your piece, one of the best articles of the session lost not a little of its attractiveness because the author was unable to decipher his writing so as to read it in an easy manner.

Be brief, others are anxious to speak as well as you. Enthusiasm is a good thing but when a doctor talks an hour he wearies his audience and cheats his colleagues.

Be sure you have something to say when you talk, then say it concisely, clearly and but once.

In discussions don't repeat the author's paper agreeing in all points; briefly allude to them, and dwell only on something not yet mentioned.

If a doctor reports a very uniquecase, d on't dampen his ardor by always havi ng one just like it. If you habitually do so you will be regarded as an hereditary exaggerator—*South Cal. Practitioner.*

## ORIGINAL ARTICLES.

### THE FORMATIVE PERIODS OF MEDICAL NOMENCLATURE.

A. L. BENEDICT, A.M., M. D.,* Buffalo, N. Y.

The present is a time when what may be called the medical dialect of the English language is rapidly growing. It is worth while to pause and consider whether those of the medical profession who are coining new words, and the rank and file who are accepting them and giving them currency, are doing justice to themselves and to succeeding generations among whom the present output of terms will continue to circulate. Let us admit at the outset that it is infinitely nobler to be able to recognize a disease and to treat it skillfully, than it is to be faultless in the choice of language with which to describe the various steps towards the desired end. Never-the-less, it must be remembered that medicine is a profession, not a trade, and that something more is demanded of the physician than the mechanically correct performance of a task. There is much excuse for the Bostonian, who in reply to the question: "What did the doctor pronounce your trouble?" said, "He pronounced it eczéma, and I discharged him immediately." The man who wishes the esteem of his associates must be more than utilitarian, and especially must be correct in details of language, whose use or misuse betrays his standing to every casual acquaintance.

In the infancy of any branch of science, there is an opportunity for the reasonably careful observer, even though he observes superficially, to discover an enormous mass of new facts, and there is a corresponding rapid increase in technical words and expressions. Then there is a period during which facts are correlated and assimilated, while the terminology is revised and improved but without much addition. Again there comes a time when, with more exhaustive methods of research and with concerted efforts to penetrate beneath the surface facts, a second demand is made for a new issue of verbal currency with which to expedite the interchange of newly acquired ideas. No other branch of science has demanded so great an increase of terms as has medicine, and the explanation is easy. In the first place, medicine is not an entity, but the bringing together of all parts of chemistry, botany, anatomy, physiology, microscopy and many other subjects that can have any bearing, practical or theoretical, on the healing art. In the second place, other useful arts and sciences content themselves with a terminology for general principles and a few descriptive structural terms. For example, the botanist uses names that will indicate the classification of a plant and the function and shape of its component parts, but his description fails to reproduce an image of the particular plant which he has in mind. On the other hand, in the matter of anatomy alone, the physician must have a terminology that shall express vividly and exactly the most complex relations of structures, compared with which the boundaries of states and countries, the course of

*Consultant in Digestive Diseases, Riverside Hospital.

rivers and railroads, the location of mountain ranges and other geographical land-marks are of the utmost simplicity. In other medical sciences, like necessity exists for concise and definite expressions. It is not surprising, then, that the average medical student spends at least a year in acquiring a fairly accurate knowledge of the meaning of words.

The first period of word-building for medical science was necessitated by anatomical research, the tendency toward the use of standard preparations of drugs and the recognition of typical groups of symptoms as marking certain diseases. The perspective of time enables us to disregard the long intervals which really separated the efforts of different investigators and to consider the results of several centuries, as simply a step towards the formation of a medical vocabulary. The nomenclature of this period is almost entirely Latin, and fortunately, the educated men were so familiar with that language that their terminology is almost beyond criticism from the grammatical standpoint. It is a curious fact that we have retained the original Latin forms in speaking of bones and muscles, while we have anglicised the names of vessels, nerves and most ligaments. For example, it is customary to say, "extensor communis digitorum," instead of "common extender of the fingers," but we say, "femoral artery," rather than "arteria femoralis."

The question has often been raised whether a nomenclature taken almost bodily from a foreign language is best adapted to the needs of the profession, but there are excellent reasons for upholding it. It is convenient to employ terms that are unintelligible to patients themselves. Most clinics would be positively brutal if the lecture were given in language that the patient could clearly understand. Note how the disease vulgarly called 'pox' has been in turn spoken of as syphilis, specific trouble and finally lues, in the attempt to keep ahead of the patient's knowledge of terms. Note also that consumption—itself a Latin euphemism has been translated into Greek as phthisis, pronounced successively teesis, tisis and thisis, that these words have been replaced by pulmonary tuberculosis, while since Koch's discoveries have become widely known, all sorts of circumlocution have been used to elude the increasing knowledge of the laity. Another reason for preferring that a scientific nomenclature should be drawn from foreign sources is that familiar words become encrusted with secondary meanings which connect them with other words and tend to conduct the thought away from the object to which it should be confined. The word fibula, for example, suggests to the anatomist the outer bone of the lower leg, and nothing else. Literally, it means a clasp, buckle, connecting pin or bond; but none of these English expressions would be sufficiently definite. The best reductio ad absurdum of the use of a home-made nomenclature is afforded by the Germans. By a curious anomaly, they use side by side a much purer medical Latin than we do, and such verbal monstrosities as heart-bottle for pericardium, slime-skin for mucous membrane and beat-vein for artery. Perhaps, it is because the educated Germans have almost a speaking familiarity with Latin that they are so much less pedantic in the use of it.

But the result is a practical disadvantage to English-speaking physicians, for, while the medical literature of other countries has a technical nomenclature almost identical with our own, that of Germany—the most valuable of all—presents great obstacles to the translator.

An objectionable feature of medical nomenclature, not alone of the first period, but of the present, has been alluded to in these words by Dr. Oliver Wendell Holmes: "If a doctor has the luck to find out a new malady, it is tied to his name, like a tin kettle to a dog's tail, and he goes clattering down the highway of fame to posterity with his æolo attachment following at his heels." It is a very doubtful honor to have one's name go down to future generations to be cursed by successive classes of students who are already overworked to remember necessary facts without being burdened with biographical association. The injustice is often done of immortalizing the name, not of the real discoverer, but of some one who has brought his discovery into prominence, or who has been accidentally connected with it. Moreover, the conspicuous anatomical land-marks, which have been made to serve as monuments to the memory of early dissectors, are such as anyone would notice. The fissures of Sylvius and of Rolando in the brain, can not be said to have been discovered, except in the sense that one

might discover that animals breathe or that the sun rises. No one thinks of naming part of the brain after Burt G. Wilder or W. W. Keen, although either has done more solid work in that part of anatomy than all the older anatomists combined.

The second period of growth in the vocabulary of medicine marks the renaissance of medical science. The systematic use of the microscope developed, almost created, the sciences of histology, embryology and pathology. Ingenious instruments and practical experimentation cleared up doubtful problems in physiology and established pharmacology — the exact knowledge of the action of drugs. Bacteriology opened new worlds of conquest and its practical expression, the use of antiseptic methods to prevent wound infection, made possible the surgery of the brain and abdominal cavity. Critical study revealed a host of new facts and new words were necessary to mark the paths of a multitude of pioneers in every field of medical science. In the preparation of a recent medical dictionary, there was assigned to one man simply the collection of words referring to the modern discoveries in the physiology of the liver, gall-bladder and their ducts and to the new operations on that part of the body. We are almost compelled to designate modern operative methods and clinical discoveries by proper names. It would take a sentence to locate McBurney's point, a paragraph to explain the Argyll-Robertson pupil, a chapter to describe Emmett's operation. Such a nomenclature is photographic in its convenience and accuracy. A less arbitrary and more technical description would be like a painted portrait, more artistic but too wasteful of time and less reliable as to details. Yet it must be hoped that this tendency to use personal names will be held in check and regarded as intrinsically evil.

The question between a foreign and a home-made terminology has been decided in favor of the former by the vote of almost every one who has had occasion to add a word to our already large vocabulary. A few imitators of German embryologists have familiarized us with *mid-gut* and *hind-brain*, but it is significant that most of the new words are of Greek origin and not even of Latin! Why do we say *bacteriology*, *micrococcus*, *pyo-phylactic gastrostomy*, *enteralgia*, *salpingitis* and *neuroma* instead of their Latin equivalents? The reason is not hard to find. English is only nominally a Germanic language; after the first few hundred words necessary in gaining food and shelter, the bulk of our dictionary is filled with words more or less directly taken from the Latin. The most ignorant would recognize nothing stilted or foreign in such words as *city*, *street*, *cause*, *fact*, *add*, *hour*, *school*, *real*, *solid*, *pen*, *table*, and yet all of these are but slightly changed Latin words. Unconsciously, the demand for foreignness, for separation from commonly used expressions, has been so urgent in the case of new scientific discoveries needing names, that not even Latin has been able to satisfy this demand and recourse has been had to Greek. If one could read the future, it would be interesting to know if the next great leaps of medical science will leave their imprint in derivatives from Hebrew or some other language.

History repeats itself. When the English language had assimilated the Latin words which came to it through the Norman conquest and the scholastic writers of the Elizabethan era, the unique phenomenon was presented of a double language having Saxon and Latin equivalents for a great many ideas. So in our present medical terminology we are compelled to have both a Latin and a Greek vocabulary. Thus we say *pulmonary* but *pneumonitis*, *intestinal* and *enteritis*, *cæcum* and *typhlitis*, *vesical* and *cystic*. In many instances English, Latin and Greek synonyms are all in common use, for example blister, vesicant, epispastic; sweat, sudorific, diaphoretic. The facility of the Greek language for forming compounds and supplying prefixes and suffixes has doubtless favored its use in science. Thus we have *ectoderm*, *mesoderm*, *entoderm*, referring to the outer, middle and inner membranes or skins from which the embryo develops; *epidermis*, meaning the covering upon the true skin; *hypodermatic*, describing an injection under the skin; *dermoid* (better *dermatoid*) referring to a tumor whose contents are skin-like; *dermatitis*, meaning an inflammation of the skin; *dermatoma*, a tumor of the skin; *dermatology*, the science of skin diseases; and many others. So an inflammation of any organ is denoted by the termination *-itis* preceded

by the name of the organ; the tumors end in *-oma*; the aches in *-algia*, the discharges in *r-rhœa*. These few illustrations will show how wonderfully plastic the Greek language is—unfortunately it is not always moulded by skillful hands. The standard of classical education has declined since the first period of growth of the medical vocabulary. Whereas the men who bestowed anatomical and pharmacal names could write and speak quite fluently a Latin which was correct in its inflections and syntax, if not in construction, there are at present too many advantages in scientific and practical education to leave much time for the classics. The speaking of either Latin or Greek is an almost unheard of accomplishment, and few of the most erudite, unless actively engaged in teaching these languages, can do more than stumble through a translation of the simplest classical writings. The law of the state of New York, which has been enforced only against those who began the study of medicine after June 13, 1893, requires for admission to a medical college simply a common-school education. One would naturally think that the only objection to the law would be that by making such a requirement, it would be construed as formally approving of the minimum education. On the contary, it was bitterly opposed, not only by some of the prospective students but by many practicing physicians and a few medical colleges, on the ground that it required too much. It was carried only by long continued, hard work on the part of its advocates, the better class of physicians, and was subsequently threatened by amendments which would have delayed its operation and crippled its effectiveness. Yet New York, whose law requires little more than a self-respecting ditch digger would consider necessary, is surpassed by few states in the matter of preliminary medical education, and, astonishing as it may seem, a perceptible improvement has followed the enactment of this law. It must not be supposed, however, that the progress of medical science or the standing of reputable physicians and surgeons can be judged by the educational minimum legalized in this state, or, by the greater depths of ignorance permitted in others. Almost without exception, the men of prominence in the profession or those who come in contact with the intelligent part of the community, are well prepared for the work in which they are engaged. They set the pace for medical and surgical progress, while those who would be affected by any possible legal requirements follow as well as they can and are not missed if they drop behind.

Yet the fact remains that the medical profession has not always acquitted itself creditably in following the precedent of deriving its new words from the Greek. In a recent paper on "The Spelling of Some Medical words," Dr. George M. Gould, in the *Medical News* says: "When a word is desired, the modern writer snaps out his Liddell and Scott, gets some words that best suit his purpose and shakes them together in his etymologic basket until they cohere into some sort of unity, not infrequently a very ludicrous one." This sentence pithily expresses the fact that, while the rank and file of the medical profession are unable to do more than memorize arbitrarily the terminology provided for them, the men who create and supply the demand for fresh words, depend for the most part on the half-remembered remnants of an early training. Mistakes are inevitable. For example the word laparotomy, which is almost universally understood as involving an opening into the peritoneal cavity through the middle line, means a cutting into the flanks. Exception has been taken to the word symphysiotomy, which applies to the separation of the innominate bones at the pubes so as to allow a springing apart of the pelvis. The word symphysis means a growing together and should not be used in a new compound in the limited sense of the union of the pubic bones. Yet the alternative suggested, pubeotomy illustrates one of the most glaring sins against literary decency, for it involves the miscegenation of a Latin and a Greek word. The word ovariotomy is another mongrel of this description. It should be replaced by the word oöphorectomy (egg-bearer outcutting) but is retained on account of the arbitrary distinction between an operation for the removal of a large ovarian tumor, and one for the removal of normal and slightly-enlarged ovaries. Tonsillitis and uvulitis are similar misunions of Latin and Greek elements, and should be replaced by amygdalitis and staphylitis for the Greeks used amygdale, whose literal meaning is

almond, for tonsil, and staphyle—a bunch of grapes—for uvula. Perhaps the most flagrant illustration of this kind is endo-cervicitis, whose perpetrator must have had an endo-head-itis. Endo-trachelitis, meaning literally inflammation of the inside of the neck, is at least all Greek, but is objectionable in using the general word for neck in a special sense. Cervical endo-metritis would be preferable to either and not much longer. Many similiar errors might be mentioned. Some of the worst illustrations of the tendency to say in one long word what might better be expressed in a few short ones, are found in the description of gastric neuroses, hyperacid, an-acid, hypo-acid, etc., and in the word uricacidæmia, which is only one step removed from grape-sugar-æmia.

In spite of the errors alluded to in this paper, there is good reason for congratulation that the rapid growth of medical terminology has been on the whole, healthy and symmetrical. To guard against the perpetuation of faulty word-forms, the writer would suggest that some of the International, or even American medical congresses appoint a committee to examine the credentials of new terms, and to report upon words to be discarded or modified. The same end could be reached as well, though less formally, by concerted action on the part of editors of medical journals. No other class of physicians is so widely and recently informed, and no other has the same advantage of a position from which instruction of their colleagues is so readily given and so freely accepted. An editorial committee could recommend changes as wisely as any having the authority of a powerful medical association, and lists of words to be adopted or expunged, could, through the columns of the journals, be given wide circulation. Moreover, teaching by example as well as by precept, would be possible in all parts of the journals that are under editorial control.

## DISPUTED POINTS IN PELVIC PATHOLOGY AND SURGERY.

JOSEPH PRICE, A. M., M. D., PHILADELPHIA.

In the medical profession very many of the old school are unwilling to accept the attested scientific facts of the new school. They are usually men so saturated with old ideas and beliefs that to them every new ideal, every revelation of a new truth in medicine or surgery is a medical or surgical heresy. And then we have the irreverent, iconoclast, the sacred bull amid sacred china, the man whose position is gained and kept for a little while more through the sweat of his jaws than the sweat of his brain. He is not a votary of either the old or the new school, he is a seat of learning all to himself—all his facts are his own—he has no interest in, and nothing to do with other people's facts. These nondescripts are usually mere bundles of little aggravations.

A few years ago intra-uterine applications and tinkering were practically abandoned by a large number of prominent gynecologists, by the men who recognized that gynecology had not reached the dignity of an exact science, that they were yet in their primers as to many needed lessons, to whom the diseases of women were a profound study—not simply a diversion, idle novel reading.

Many of the old methods of procedure were found useless and often dangerous; they were but the out-growth and crude expedients of emergency to be condemned by more enlightened experience. Most authors in discussing disease, treatment and procedure have a few accidents and not a few deaths to cite.

There still are those in the young school claiming to revise procedures without a careful study of their earlier history, who lose sight of the fact that these procedures had been very studiously tested by men much more thoroughly experienced and competent than they, without too much tension upon their modesty, could claim to be.

For awhile the enthusiast, the fresh graduate, critic and reviewer, the new-

fledged, fresh-blossoming gynecological recruit, with few or no experiences, heralds and claims everything for his particular application, method of dilatation, irrigation and drainage. Later he ventures to predict that the uterus will be removed in all cases, an organ that has little to do with the patient's condition in very many instances. Again, early in his trial trips, he washes the septic uterus once an hour, examines all puerperal cases about the tenth day, and makes an application to unhealthy cervix and to the cavity of the uterus.

A few men practically interested in both practical obstetrics and gynecology find such tinkering dangerous. The exceptions commonly seized by disputants are retained placenta or neglected abortions. Nearly all active practitioners have such cases to treat. They are to them not something guessed at, but characteristic symptoms to be promptly dealt with. The general practitioner as well as the specialist fully realizes the importance of emptying the uterus of debris, of all decomposing particles. There is an apportunity in these cases for grave error in diagnosis and treatment.

The absence of one or more periods, pain and prolonged hemorrhage, the passage of clot, shreds of debris or decidua, is not always an abortion, but often an extra-uterine pregnancy, or may be occasionally due to suppuration of tubes and ovaries. I have repeatedly removed a ruptured tubal pregnancy a few days after the curette had been used very freely by a physician mistaken as to the real character of his case.

Men who now deny the mortality following the 'let alone' or palliative treatment of tubal and ovarian disease, a few years ago, while interested in pelvic surgery, made repeated reference to the chronic invalidism, long suffering and numerous deaths in these cases and urged upon the profession through elaborate papers the very frequent occurrence of neuroses, numerous sinuses above and below, and the tedious convalescence, if they recovered at all, and also the impossibility to relieve, cure or save life without resort to surgery. There was a large number of these cases then as now. Now some of these same authors contradict their own teaching. Now they claim that they can be relieved and cured and conception follow, this notwithstanding they know or should know that extensive disorganization has long since destroyed all possibility of conception.

Incisions, tents and other methods of treatment have resulted in a large number of cases of peritonitis and abscess. A small group of cases are recorded as dying of tetanus as a result of the use of the tent.

I have been asked to see patients by men bitterly opposed to operative interference. In spite of their well-directed treatment the patient grew worse, their condition the more alarming. Some I found dying, others very ill. Some are saved by prompt interference, others die before the family or friends have time to consider the matter fully. The physician or physicians make post-mortems in some cases and bring me the specimens, telling me that the operation would have been impossible, that the complications were too great, that the post-mortem was only possible with knife and scissors. This has occurred repeatedly in this city and about it, also in neighboring states. We now save large numbers of women who would die of general infection in a few months under so called conservative treatment, or the application of those delusive devices, which deceive patients and friends by affording only temporary relief.

They are saved by prompt, painstaking and skillful surgery. Delays are wholly responsible for infection, emaciation, renal disease, coughs, phthisis and extensive bowel complications, all of which troubles increase our mortality or augment the risk and complicate the surgery in a number of those cases that change hands and submit to operative interference at the eleventh hour.

The importance of pathological knowledge is vital, for without it it will always be difficult for a surgeon to decide when to act, and when not to act. Again, thorough practical knowledge of diagnosis is essential to determine what line of treatment promises the best results. Without such knowledge or skill there is always danger of a surgeon doing mischief. When he combines ignorance, want of skill, or both, with a fondness for surgery, he is a dangerous man in any community. Take any old salt or tar and he will know and do better. He would intuitively recognize the extent of his knowledge, the limit of his powers, and would keep hands

off and not incur fearful responsibility or invite calamity. These neophytes in surgery illustrate the proverb—"Fools rush in where angels fear to tread!'

While operators continue to give so much prominence to simple pain and tenderness, chill and fever, they will continue to make errors.

It is important to locate the uterus, to determine accurately its relation to accumulations in the pelvis, fixed or movable, lateral or posterior, size, fixation and consistence, and the physical characteristics of lateral masses.

Simple tenderness and pain is misleading.

An occluded tube with retention of blood, pus or water is about always fixed by simple or extensive adhesions. The history of such cases, with the common objective signs, are important and are of great assistance in forming an accurate surgical judgment of what we have to deal with and how to deal with it.

I make the statement without fear of its being successfully controverted, that diseased, disorganized and occluded tubes, with retention, never return to health or perform their physiological functions. The numerous references to case, of diseased or occluded tubes being followed by conception is simply an error in pathology and diagnosis.

I have repeatedly removed a diseased or occluded tube of one side, recognized before operation, and have stated to the patient that probably the removal of the offending side would favor conception—which followed in a number of cases.

I insist upon examinations without the use of an anæsthetic. The coöperation of the patient, is important and sufficient.

In dispensary work the student soon becomes familiar with tubal and ovarian diseases without the use of anæsthetics. He tells quickly what he finds, and on which side the trouble is most marked, and this without complaint of pain on the part of the patient.

Unfortunately, too many operators in the past have been influenced by history, neuroses, hysteria, sterility, back-ache, dysmenorrhœa—by symptoms rather than by objective signs. This is an error, and is the source largely of the disrepute of much of this work, and the confusion that should not prevail. With accurate knowledge of pathology and diagnosis, there will be less wrangling over and less mistakes in our surgery.

We all realize the importance of a more uniform consensus of opinion, and the importance of this society maintaining the principles of sound pathology and surgery. Our medical societies are in a sense operating rooms where object lessons are given. They are the educating and re-educating institutions of our profession. The refinements of surgery and obstetrics are obtained by the concentration, the consecration of time, labor, thought and energy to practical work—by eschewing conservative methods, tapping, incising, fancied ingenious methods, novel contrivences, parade of tables, strained or unnatural positions, terraced sutures and much of our bacteriological lore.

We have done a great work as a society, both in obstetrics and surgical gynecology, a work of great value to science and suffering women. As ardent votaries of a science we have not been groping our way in a spirit of blind faith, we accept only that, the verity of which is confirmed by experience and stands the tests of appeal to experiment and observation. We have grappled with complex problems many of which have not yet been settled to our satisfaction. We may yet be dealing with but elementary truths, but we would deal with them so conscientiously, so studiously as to get down to the deeper underlying truths. We meet in our societies to get at facts, the best logic of our science.

All our triumphs over disease must come of our improved knowledge, our advanced skill in our work. If we have increased the average of human life, it is because we know more and better and promote more strictly and scientifically the conditions of health, than did our forefathers. And if our success in dealing with diseased conditions is greater than theirs, it is because we have used wisely the many lessons they left us as rich legacy, and with vigor and spirit have added to the knowledge they have transmitted. Better know more of nature and the better obey her laws and provide against pestilence in its varied forms. Through our better facilities we have a more accurate and broader knowledge of the laws of hygiene, know more of chemistry, of human anatomy, of physics; know more in every department of medical science. Yet splendid as may

have been and are our facilities, marvelous as has been our advances along all lines, many and arduous will be the steps before the capstone is laid.

Under the compendious title of medicine there is included so very much, that we may well stand appalled at what is before us. We look upon our society as a potential agency, an inestimable aid to our efforts in the immense work. In medicine there are no serene retreats—all its paths are rugged and thick strewn with inviting mysteries; with problems deep as life itself, and as old, which through all our advances we have been solving only in fragments.

Our society has done more than stimulate our efforts, it has awakened higher conceptions of our duties and possibilities; we have gone out from it with the strength, even of our clashes in which it has given us.

## COMMUNICATIONS.

### UNILATERAL PLEURISY WITH EFFUSION.*

J. M. ANDERS, M. D., PH. D.†

I have to-day two cases to show, one being a typical and the other an artificial case of pleurisy with effusion. The clinical history of the first is as follows:

M. C., male, aged thirty-seven years; birth-place, Italy; social state, single; family history, father and mother dead; causes of death not known. He has one sister living and well. No history of hereditary disease in the family.

Previous history: When a child he had measles, and later on an attack of chills and fever, but since that time has been in good health until the onset of the present disease. Two years ago he came to this country, but was unaffected by change of climate, and was always healthy up to the present time.

History of present disease: On December 23, 1893, the patient was seized with a sever rigor, followed by headache, intense lumbar and general muscular pains, which continued during the following week. Although unwell and unable to work at this time, he remained out of bed. One week later, December 31st, a sharp pain was experienced in the region of the right nipple, shooting backward to the scapula. On admission, January 3, 1894, the pain in the chest was less severe, accompanied by a dry, hacking cough, with slight expectoration. Respirations were somewhat increased and jerky in character, and some dyspnœa was noticeable, with cyanosis of the lips, eye-lids and finger tips.

Physical examination revealed the following: On inspection, the right side showed fullness with slight bulging of the intercostal spaces, expansion being perceptibly diminished on that side.

On palpating, tactile fremitis was absent over the lower two-thirds of the right lung, being somewhat exaggerated above this. Percussion, with the patient in the erect posture, showed absolute flatness below a line extending from the right nipple in front to the angle of the scapula posteriorly.

On ausculting, the breath sounds were found to be entirely absent over the affected area, and this in conjunction with the other physical signs established the diagnosis of pleural effusion.

To-day, as the patient lies before us, we will begin a systematic examination, by inspection, palpation, percussion and auscultation in regular order. The chest is a well-developed one, the muscles being well-defined. The two sides are symmetrical, with perhaps the slightest degree of bulging to the right. The respirations are still somewhat hurried and jerky in character. The movement on the right side is upward and downward rather than upwards and outwards, as occurs during normal respiration. The apex-beat is plainly visible, being displaced to the left, the pulsation extending to the anterior axilary line. There is no enlargement in the area of cardiac dullness, but displacement to the left has occurred. Several theories are advanced as to the cause of this displacement. It was thought formerly to be due to fluid pressing against the heart, but this has been disproven by the fact that it may, and often does occur with the *beginning* of the peural effusion. Among many explanations is one given by

* Clinical Lecture delivered in the Philadelphia Hospital.

† Prof. of Medicine Medico-Chirurgical College.

Garland, of Boston, which is as follows: The heart lies between the lungs, suspended from the third dorsal vertebra. The lungs being expansive retract on the two sides; that on the side of the pleural effusions has its elasticity impaired, hence its traction force is diminished. The healthy lung being unimpaired retracts and draws the heart to that side. The displacement being further increased by the effusion.

Later on intra-thoracic pressure becomes evident; the elasticity of the lung is destroyed and direct mechanical pressure results. After absorption of the exudate, displacement may be caused by pleuro-pericardial adhesions. Diminished expansion occurs, producing a vacuum and causing a sinking-in on that side of the chest. The intra-thoracic pressure on the affected side is lessened and this, together with the normal atmospheric pressure against the chest wall and the normal intra-thoracic pressure on the sound side, are factors which aid in the displacement. The spleen and liver are often slightly out of their normal position and displaced in a downward direction as detected by palpitation. During health the retractibility of the lungs exerts a traction force on the diaphragm below; this force is destroyed by an effusion filling two-thirds of the chest, or causing considerable intra-thoracic pressure the diaphragm becomes depressed, thus displacing downward the liver on the right side and the spleen on the left. Such cases should be watched with great care.

We will now have the patient sit up. On palpating over an effusion the entire hand should not be used as the boundary line between liquid and lung tissue cannot well be distinguished. Use the tips of the fingers, begin above and proceed downward. In this case I find posteriorly tactile fremitis unimpaired downward to one inch below the angle of the scapula, below that being entirely absent. This is not an absolute sign of effusion, as the entire chest may be filled with fluid and yet some fremitis be present, owing to fibrous bands in cases of chronic pleurisy transmitting vibrations from the lungs to the chest walls. On pressing the finger-tips in the right axilla between the ribs, and the latter tend to converge and do not expand as normally, the respiratory movement is also felt in an upward and downward direction. Percussing anteriorly shows flatness beginning on a level with the nipple and extending downward, with the patient in the sitting position. Percussion over a liquid should always be performed lightly and delicately, the sense of resistance imparted to the fingers often being felt distinctly. Above the nipple line a semi-tympanitic note is produced, showing exaggerated percussion resonance, above the effusion. Skoda's resonance which is a higher pitched note, is only heard when the effusion reaches up to the level of the fourth rib or higher. It also may occur under other conditions. Posteriorly percussion gives below the angle of the scapula a flat note, *i. e.*, one entirely without resonance. In pneumonic consolidation dullness may be obtained, but not absolute flatness, because the alveoli, although filled with exudate may transmit vibrations to the bronchial tubes. Complete dullness is not the same as flatness. In pleurisy with effusion we have absolute flatness; in pneumonia dullness alone may be present. From one to one and a half inches above the level of the effusion in this case, percussion gives a dull note because the lower border of the lung contains less air than normally. This may be caused by congestion or in some instances by œdema of that portion of the lung. Higher up we have exaggerated resonance, the note being elevated in pitch and vesiculo-tympanitic in character. The line of flatness in pleural effusions is not level when the patient sits erect, but gradually rises from the spine toward the axilla, being highest just behind the mid-axillary space, then falls as I proceed toward the sternum. This is an important sign in pleurisy. In a beginning effusion the liquid first comes in contact with the diaphragm, but this cannot be detected by physical examination, flatness on percession being first noticed in the axilla. Some authorities state that the upper line of flatness takes the form of the letter S, but more commonly a curved line which presents its convexity toward the head, is apparent, dullness changing with the position of the patient. In some instances the fluid presses on the diaphragm below and is confined between that muscle and the base of the lung, being prevented from changing its position by the elasticity of the latter. In hydro-pneumo-thorax the liquid moves much more readily because

the elastic force of the lung is lost. In diagnosing a pleural effusion, percussion signs are of the greatest importance, especially dullness changing with the position of the patient, which is apparent in this case. On having the patient lie down we find that resonance extends two inches below the nipple-line. On ausculting we have entire absence of respiratory and vocal sounds below the angle of the scapula, and on deep inspiration and speaking, sounds are transmitted feebly to the ear, although the respiratory murmur is totally absent. No friction rales are apparent because the fluid lies between and separates the pleural surfaces, although absence of pleuritic rales may be accounted for in other ways. The respiratory muscles from pressure may become completely paralyzed and total loss of motion result, as soon as the pressure is removed the muscle reacts and friction sounds may reappear. In the case before us the physical signs and clinical history all indicate pleurisy with effusion.

The subjective phenomena, such as pain in the side shooting to the back, embarrassed jerky respirations, dry croupy cough with scanty expectoration, and moderate amount of fever are not diagnostic. Displacement of the apex beat to the left, with total absence of vocal fremitis, flatness on percussion changing with the position of the patient, are of far more importance and render the diagnosis absolutely certain. But we do not have to deal always with a typical case. Pneumonia or tubercular consolidation may occur as complications. In the latter, evidences of disease are first detected at the apex or apices and progress downward. In the latter also one side is rarely effected throughout, as in the case of pleural effusion. Clinical history also aids in the differential diagnosis: In tubercular infiltration the progressive emaciation, hectic temperature, chronic cough with expectoration of purulent matter, which, when stained and examined microscopically is found to contain tubercle bacilli, all tend to establish the diagnosis without doubt. In croupous pneumonia the elasticity of the lung is overcome, compression of the alveolar structure results and we have dullness, *not* changing with the position of the patient, together with bronchial or tubular breathing and, if in the first stage of consolidation, the characteristic crepitant râle may be heard occuring at the end of inspiration. The attack begins often with a severe chill followed by high fever, extreme dyspnœa, panting respiration, cough with the expectoration of rusty sputa and on the sixth or seventh day crisis occurs, temperature drops to normal, profuse muco-purulent expectoration takes place and the patient enters convalescence. In this disease the physical signs show by inspection limited motion over the affected area, but *no* bulging of the intercostal spaces and *no* displacement of the heart or other viscera. Palpation gives *increased* tactile fremitis and percussion shows dullness, not flatness, which does not change with the patient's position. On ausculting in croupous pneumonia we have bronchial or tubular breathing all over the affected side, together with *increased* vocal resonance and broncophony, which extends to the base of the lung. This never occurs in a pleural effusion because there is a layer of fluid between the lung and diaphragm. In an effusion only when the chest is two-thirds filled with liquid may we get indistinct bronchial breathing over small areas just below the level of the fluid, together with impaired tactile fremitis and diminished vocal resonance. This has been proven by aspiration. Enlarged liver may be mistaken also for right-sided pleurisy, but in this there is no change of flatness varying with the position of the patient and no upper curved line as in a pleural effusion, together with absence of flatness in the mid-axillary region. Again the flatness due to an enlarged liver extends higher in front than posteriorly, which is the opposite in cases of pleurisy. A large abscess on the upper surface of the liver may give an arched line of flatness which, however, does not involve the whole side. In establishing the diagnosis of pleural effusion physical signs are of far more importance than the subjective phenomena.

Now, as regards the etiological factors in a case of pleurisy, in this instance the rigor, headache and severe muscular pains began one week before the development of stitch-like pain in the chest and other symptoms, thus indicating in all probability that the attack was preceded by one of influenza. Another case recently came under my notice, in which the diagnosis of influ-

enza was undoubted, being followed several days later by an attack of pleurisy with subsequent effusion. In this patient there is a history of exposure, but simple exposure does not always precipitate an attack. Very often predisposing causes are present; it is apt to be secondary to chronic alcoholism, chronic Bright's disease, although in this case the urine has been examined repeatedly and found to be normal. Acute infectious diseases also act as predisposing factors in the causation of pleurisy.

*Concerning the Prognosis:* In simple uncomplicated pleurisy when the general health is good, the prognosis as to life is always favorable. There may be, however, a rapid increase in the effusion, the heart's action or the respiratory functions may become suddenly embarrassed and death result. Relatives or friends of the patient should always be informed as to the liability of this occurrence. In some instances death has occurred suddenly and without apparent cause being demonstrated by post-mortem examinations. Finally, the serum may be converted into pus and an empyema result, thus preventing or retarding absorption, and further complicating the case. In recovery, the membranes are thickened, new tissue is formed and conditions are favorable for the development and growth of the bacillus of tuberculosis. Indeed, often the process is tubercular from the beginning and effusion results secondarily, as in the cases of so-called "tubercular pleurisy," which are very common, or, the process may begin as a simple inflammation and sero-fibrinous pleurisy result.

*Treatment of Pleurisy:* Simple or sero-fibrinous pleurisy is an inflammation, and not a transudation as occurs in hydro-thorax due to valvular heart or kidney disease, therefore, the first indication is to reduce the inflammation in the pleura, and thus limit the amount of exudation; not to get rid of the liquid. How is this to be accomplished? By local and general measures. If the blood pressure be good, give remedies that reduce the arterial tension as tr. veratrum viride, together with mild diaphoretic and diuretic mixtures. The patient before us is taking a mixture composed of citrate of potash, sweet spirits of nitre and solution of the acetate of ammonia, with additionally bashanis mixture. For the pain, opium is very efficient given in the form of sulphate of morphia hypodermically or in suppositories of the powdered drug or extract. It supports the heart and controls inflammations of serous membranes. Quinine should be given liberally, sixteen or twenty grains daily in divided doses. It also controls inflammation. Locally, mild counter irritation should be resorted to and continued through the fever. Weak sinapisms followed by poultices and protection by means of a cotton-jacket to the chest. When the febrile stage has subsided and the temperature becomes normal, promote absorption by means of moderate purgation together with the administration of iodide of potassium, and some form of iron, preferably the syrup of the iodide of iron. Diuretics and diaphoretics have not in my experience proved very efficient in hastening absorption of the exudate. Five (5) grains of potassium iodide with ten (10) minims of the syrup of the iodide of iron given four (4) times daily may be doubled or trebled varying with the circumstances attending the case. Another preparation much used in this connection is the syrup of the iodide of iron and manganese. But absorption will not always occur under medical treatment and tapping must be resorted to. In aspirating there are certain rules which must be borne in mind by the beginning as well as the older practitioner, both during the febrile stage and subsequently. Only when urgent symptoms are manifested and in cases of the gravest character should aspiration be performed during the febrile stage. When one pleural sac is entirely filled, which can be demonstrated by entire absence of Skoda's resonance and flatness reaching up to the clavicle, aspiration *must* be resorted to. If, during the course of a unilateral pleurisy with effusion, any complications should develop on the unaffected side, in the heart or lung, as demonstrated in the latter by the presence of moist rales, œgophony and impaired resonance, thus indicating œdema; or if the apex beat is displaced to the left and a murmur becomes apparent together with downward displacement of the liver and spleen and development of orthopnœa, aspirate immediately.

In double pleurisies also aspiration should be performed early. How long a

time should elapse after the temperature and active inflammation have subsided before determining to aspirate? If, on making a careful physical examination one week later no evidences of absorption can be obtained, aspirate; on the other hand, if the slighest degree of absorption has occurred at the end of that time, it will often continue uninterruptedly and disappear entirely without interferance. In subacute or chronic cases with effusion, absorption often does not begin until the fourth or fifth week or may not take place at all. In all such cases a good rule is to wait three weeks for the exudate to disappear and at the end of that time, if absorption has not begun, aspirate and remove a small quantity of fluid. This will often be followed by a rapid disappearance of the remainder. The patient before us has had some fever but no complications and as the fluid does not fill two-thirds of the pleural cavity at present there are no indications for aspirating. If after one week, absorption has not begun, some of the fluid will be withdrawn.

NOTE. One week later the internal treatment having been continued, the temperature had dropped to normal, the exudate had begun to disappear and the patients physical condition was much improved, in every respect, rendering aspiration unnecessary.

## OIL OF PEPPERMINT IN PULMONARY CONSUMPTION.

CHARLES B. WILLIAMS, A. B., M. D.,* PHILADELPHIA.

Dr. Carasso has recently published (*Deutsche Medicinische Wochenschrift*, No. 49, 1893) a new method of treating pulmonary consumption by means of the continuous inhalation of the oil of peppermint, with the internal administration of the same drug in combination with creasote and chloroform.

Dr. Carasso claims remarkable results in his treatment of cases of phthisis with the oil of peppermint: Not only were cases cured in the first stages of the malady, but even the more advanced stages, where cavities had already formed, were cured. Dr. Carasso states that if there is fever associated with this condition, it will disappear in a few days under this treatment. He ends by citing no less than thirty-nine cases of phthisis pulmonalis in which these remarkable results were obtained.

It has been already demonstrated by Braddon that the oil of peppermint has a bactericidal action, and further, it is a well established fact that chloroform possesses in a marked degree the same properties as an antiseptic. The writer was induced to give the above treatment a trial in a case of phthisis that was well advanced and had resisted almost every form of modern treatment. The patient had been given creasote in increasing doses in combination with cod liver oil, tonics, etc., without any appreciable change in his condition.

For the administration of the oil of peppermint the two following formulæ were prescribed.

℞ Creasoti.....mxcvi.
Chloroform.....mxxx
Olei menthæ pip.....mxcvj.
Spiritus vini rect .....q. s. ad. f℥vj.
M. Et fiat mistura.
SIG. Capiat drachmam unam ter in die, ex pauxillo lactis.

and as an inhalant

℞ Creasoti.....f℥i
Olei menthæ pip.....f℥ij
Tr. conii.....f℥ij.
Alcohol .....q. s ad. f℥i.
M. SIG. Inhalet gtt x. quarta quaquehora.

Carbolic acid in a somewhat smaller dose or thymol may be substituted for the creasote in this last formula.

In less than one week's time the patient returned and reported remarkable progress in his case since taking the above formulæ. His cough had almost ceased; the expectoration was diminished to a marked degree; a sharp pleuritic pain that had troubled him in his right side for some time past, had entirely disappeared. And there was a return of appetite, so that now the patient ate his meals with a relish that he had not experienced for many months. And finally he was able to resume his occupation as a carpenter at which he had not worked steadily for eight or nine weeks.

The dose of the oil of peppermint mixture has been increased from one tea-

*Ex-Resident Physician Pennsylvania Hospital; Dispensary Surgeon Methodist Episcopal Hospital, Philadelphia.

spoonful 3 times daily, to a teaspoonful every four hours, or four times daily. The patient is rapidly improving under the above treatment.

At the present era in medicine the advocates for new methods of treatment in disease are legion, but their claims for success in nine cases out of ten must be looked upon with suspicion and taken *cum grano salis.* A new drug or a new method of treatment can take rank with the old and classic remedies only when it has been found by repeated experiment and trial to cure or, at least ameliorate, the pathological conditions of the human body for which it has been employed.

Dr. Carasso has claimed great things for the oil of peppermint in phthisis pulmonalis; he cites thirty-nine cases of consumption in all its stages, every one of which have been more or less benefited by this simple drug. And, when we come to think, it has been by the use of simple drugs that the physicians of the good old times attained success in the treatment of their cases, for they used remedies that had been tried for centuries and had been proven by experience and practice to relieve certain pathological conditions. The writer thinks that at least this simple drug should be given a fair trial in order to ascertain fully whether it will effectually combat the invasions of that dread disease, consumption.

## PISTOL-BALL WOUND OF THE BRAIN DIVIDING THE LEFT OPTIC NERVE IN THE OPTIC FORAMEN; MENINGITIS; AUTOPSY.*

THOMAS G. MORTON, M. D.

John B., aged twenty-nine years, was brought to the Pennsylvaina Hospital about seven o'clock in the evening of January 5, 1894. Shortly before admission he received a pistol wound of the face; the ball completely divided the right lower eyelid, penetrated the upper maxillary bone, and passed apparently backward and to the left, when its further course could not be determined. The patient was semi-unconscious, but could be roused; he did not seem markedly shocked, but since he had been dringing heavily the symptoms were masked. Temperature was barely 98°, pulse 66, and respiration 24. He gave his name and address, but appeared unable to make further replies. There was moderate hemorrhage from mouth and nose. Breathing had been heavy, but became easier an hour or so after being placed in bed.

On admission the pupil of right eye was found moderately contrcted, but sensitive to light stimulus; the pupil of the left eye was contracted, but was immovably and widely dilated two hours later; an effort was made to determine the location of the ball by an incision below the eye. Examination of the wound by the introduction of the finger led to the conclusion that the orbit was not involved, but that the ball had passed across through the nasal cavity to the left and had entered the brain, and in its course had injured, if it had not destroyed, the optic nerve.

The following day the patient was taken before the class; he was then rational, complained of no pain, and replied to every inquiry. The movements of both eyes were normal; vision was apparently not disturbed in right eye, large and small objects being distinctly seen; left eye totally blind, pupil widely dilated, yet sensitive when light was thrown upon the right.

*January* 8. General condition less favorable; difficult to arouse; slightly delirious at night; temperature 103°; pupils constantly varying; right more contracted.

10th. Somewhat violent at times; temperature 102½°; requires to be confined in bed.

11th. Able to reply to questions, sat up in bed. The following examination was made by Dr. Thomas H. Fenton:

"*Right eye.* Pupil about 6.5 mm., somewhat oval horizontally, feebly sensitive to light stimulus.

"Optic disk fair size, somewhat oval vertically, rather dull in color, well out-

*Read before Phila. Acad. of Surgery, Feb. 5, 1894.

lined, margins slightly elevated; fundus rather deep in color; veins very full; arteries somewhat contracted; media clear, so that all details are possible, but general definition defective owing to the slight haziness of cornea; tension normal.

"*Left eye.* Pupil 4mm., not absolutely immobile but not responsive to light stimulus, either with right eye open or closed; somewhat sensitive when right is covered. Optic disk fair size and shape; definition very good; the temporal half is leaden white, devoid of vessels; all vessels contracted on the nasal side of disk and throughout fundus, which has distinctly anæmic appearance; arteries very much contracted; no structural change except just below disk margin, where there is a small horizontal hemorahage 1mm. in size; media perfectly clear; tension normal; eyes in good position; movements normal. Large ecchymosis, bulbar conjunctiva temporal side, observed today."

16th. Patient has rapidly failed, delirium has continued since last report, and he died at 11.10 with a temperature of nearly 104°.

*Post-mortem.*—The ball entered the superior maxillary bone just below the orbital rim, about one-eighth of an inch to the inner side of the infra-orbital foramen, passing upward, backward, and to the left through the nasal cavity, fracturing the ethmoid and vomer; the orbital plate of the frontal bone was fissured, destruction of left olfactory, breaking through the body of the sphenoid, tearing away the lesser wing on the left side, completely severing the left optic nerve in its groove or foramen; the ball then passed into the left frontal lobe, where it was found just inside a large wound which continued upward and slightly backward and penetrated nearly to the upper surface of the brain.

The brain tissue in and around this wound was softened and degenerated. Several fragments of bone were carried in the brain substance by the ball, which was flattened and very rough. Evidence of suppurative meningitis existed over the entire base of the brain, and the vessels of the pia mater were markedly congested.

REMARKS BY DR. FENTON.

The case as reported by Dr. Morton is not only interesting because of its extreme rarity, but because it affords an opportunity for conjoined study by the surgeon and the ophthalmologist. Nearly all the references obtainable by a careful search of the literature of *wounds* of the *optic nerve* have been studied, and no case exactly parallel has been found. The question of main importance in this part of the record is, as to how far the extent of the injury can be determined and the foreign body located by an examination of the eyes. That such examination somewhat lessened the obscurity in this case seems reasonable. The patient gave a very credible history of previous good vision in the left eye, which yet was found to be completely amblyopic; while the right, in which some disturbance was to be expected, was practically uninjured. A valuable observation made by Dr. Claytor, the resident, is that on the date of admission, January 5th, at 7 P. M., the pupils were of equal size, and that two hours later the right was contracted and the left widely dilated. The eyes were in good position, the associated movements were normal, no loss of motility, no impairment of sensibility, no surface anæsthesia, no hypernæsthesia. Externally, then, there was nothing but the inequality of the pupils, and the ecchymosis of the bulbar conjunctiva in the left to serve as a guide. It must be remembered that the first examination which could be secured was made five and a half days after the injury. It is reserved for the opthalmoscope to give some suggestion as to the scope of the injury and the direction taken by the bullet; more especially because the atrophy, though not complete, was clearly of recent origin, and not the result of long-standing disease. This suggested that there had certainly occurred, as stated at the time, a hemorrhage into the sheath, and, in all probability, a nearly complete division of the nerve. This view was further confirmed by an examination made on the morning, and again on the evening of the 14th, when it was found that the vessels were still more thread-like and the optic disk paler; right pupil oval as before, 6 mm., left 8 mm., circular. It seemed quite certain, therefore, that the point of injury was quite well back, because, as Fuchs says; "It is only when the optic nerve has been injured so far forward that the central vessels are at the same time divided that characteristic opthalmoscopic symptoms

can be made out at once. In such cases there develops immediately after the injury a picture analogous to that of embolism of the central artery. The arteries of the papilla and the retina are bloodless, and the retina soon becomes clouded—a sign of its death." As then expressed, the examination of the eyes externally and internally seemed to favor the surmise that the track of the bullet was to the left and upward, rather than backward and downward, although the precise route and the extent of the injury occasioned by its passage could not be determined. The occular state certainly did not suggest trouble at the base. An interesting case strengthening this belief is furnished by Benson: "Perforating gunshot wound of the right eye. Immediate collapse of ball—followed in a few seconds by complete amblyopia of the left eye. Opthalmoscope showed a simple athrophy with no thickening of the coats of the vessels, which were very small. * * * There were no symptoms of central mischief."

It is evident that the most important appearance in this case was the peculiar condition of the optic nerve and retina; although the disturbance of the pupils seemed to indicate some injury to the oculo-motor and the fifth nerve. This lent more credit to the case because, as Mitchell says (*Injuries to the Nerves*): "Muscular injuries of the mortor nerve of the eye which do not at once involve loss of life are rare." It is interesting to add that this quotation is taken from an account given of a case seen by the author in consultation with Dr. Morton, in which he, the author, states that the case stands alone in the history of oculo-motor-nerve esions.

## A FURTHER COMMUNICATION UPON THE USE OF CARBOLIC ACID.

OSCAR H. ALLIS, M. D., PHILADELPHIA.

One of the results of my article on "Carbolic Acid," read before this Society in October last, was the reception of two practical and interesting letters upon the same subject from physicians who were no strangers to the valuable services attainable by the proper use of the drug. By permission of the writers I am permitted to present their views before the Society.

The first is from Dr. D. H. Brodnax, Brodnax, La.

"In 1868 I came near shooting off my right wrist. The explosion of the gun was so near that it set fire to my shirt. I was, therefore, suffering not only from a severe traumatism, but also from a painful burn. Dr. Hart, of Pickins, dressed the wounds and burns with a mixture containing ten per cent. carbolic acid in linseed oil. The pain ceased, and I slept well all night. Dr. Hart remarked as he dressed my wounds, 'You are the first man in Mississippi to have a wound dressed with carbolic acid. This was twenty-five years ago, and during that time I have never found a drug to take its place. Other so-called 'antiseptics,' have been given a trial, and that is all.

"No part of a physicians experience is more valuable than when he is the sufferer; and you will pardon me if I add one other personal experience. In 1880, while soldering a broken tin pipe, I accidentally spilled same molten solder on my hand between the thumb and first finger. I flirted off the mass, about the size of a silver dollar, which took the skin with it and caused most intense suffering. Near at hand stood a bottle of carbolic acid. I took the bottle, and with the cork wet with the drug, smeared the fresh wound. This was too slow business, so I inverted the bottle and poured some of the acid into the wound. As if by magic all pain disappeared, the burning and smarting stopped, leaving a sense of refreshing coolness. What surprised me quite as much as anything else was my ability to finish the work that I had begun with as much ease and unconcern as if nothing had happened. The cure, too, was prompt and uneventful.

"My next case was a woman seventy-five years of age. She had burned the upper surface of the foot so severely by upsetting scalding water, that when the stocking was removed the cuticle came with it. The poor woman was in great agony when I arrived. The raw surface was fully eight inches long by five inches wide. I

took a feather which I had picked up as I entered the yard, and with it spread the undiluted acid over the entire raw surface, and extending the application over the parts adjoining and which were less deeply burned. In a few seconds all pain ceased, and the patient remarked, 'It feels as if cold water was being poured over it.'

"The third application was to a child three years old, who, while at the breakfast table, pulled the coffee-pot over, emptying the contents into its bosom. Its clothing was removed, leaving the neck and breast of the child denuded. I immediately applied the officinal strength of carbolic acid to the raw surface, covering also the unbroken blebs with the same. Pain ceased almost instantly, when the child permitted me to cut the blebs and paint them without a wimper.

"My after-dressing to the burnt surface is very simple. I apply directly to the raw surface absorbent cotton, which I retain in place with a bandage. This is the first and usually the only dressing, for when it comes off the part is healed.

"As my practice has been of a general character, I have not had a large number of any one class of cases, but think that I have used the carbolic acid in at least twenty burns and scalds. Two more cases that I recall may interest you. A man was burned by a jet of steam that skinned the forearm from the elbow to the wrist. The carbolic acid was applied, and with the same result, the man remarking, 'I thought I was in for two weeks, but I'll be at work again in the morning.'

"A child, one year old, got a live coal in the bottom of its shoe. The burned area was the size of a five-cent piece, and deep. The child was nearly frantic with pain. I dipped a small piece of cotton into the pure acid and pressed it into the burned hole. I *counted* eighteen seconds, when the child stopped screaming, and, looking at me, said, 'It done; it has stopped hurting.'

"I always keep the pure crystals on hand; and to them add, when I require their use, just enough water to dissolve them, possibly ten per cent. This is strong enough to remove the skin from healthy parts. I do not add the water to dilute the acid. When it is deliquesced, as it sometimes is, I use it without any water.

"While, probably, carbolic acid has no rival in its curative action upon burns and scalds, its medicinal influence does not stop here. In sciatica I have found that the hypodermatic injection of from five to ten drops of a solution of twenty drops of carbolic acid to the ounce of water carried down to the seat of pain produces almost instant relief. So, too, in carbuncles and boils, I take a solution of from twenty-five so fifty drops to the ounce of water and inject deeply into the inflamed area a couple of drops in three or four places. On the following day the injection is repeated if necessary. The inflamed area is covered with a little absorbent cotton soaked in:

℞ Carbolic acid..... gtt. xxx.
Tannin..... ʒiv.
Aquæ..... ʒij.

By this means the morbid process is arrested and resolution promptly takes place.

"I treat gonorrhœa with injections of the strength of ten drops of carbolic acid to the ounce of water, giving also *per orem* two or three drops three times a day. Cure usually in about three weeks.

I have never but once used it upon a freshly-cut surgical wound, as Dr. Gardner suggests. In this case I removed a urethral caruncle of large size, and which was an obstacle to micturition. After clipping off the growth with scissors taken from the lady's work-box, I immediately applied undilute acid to the cut surface. The pain, smarting, and hemorrhage ceased promptly.

In regard to the use of the deliquesced carbolic acid in burns, Dr. Gardner confirms what Dr. Brodnax claims for it. He says:

"While the Alabama and Chattanooga Railroad was in process of construction, from 1869 to 1874, I, as surgeon to the road, had between five and six thousand men under my care. Among the injuries burns and scalds were frequent and often serious. These would vary in size and depth, sometimes involving the extremities and a large portion of the trunk. One foreman, in particular, had a large part of the back and a lesser amount of the front portion of the trunk, with portions of the legs, seriously burned. On removing the clothing, large portions of the skin came off with it. His condition was lamentable in the highest degree. Morphine was freely

administered internally. On the bed upon which he was to recline, clothes soaked in carbolized oil were laid. Where the blisters were unbroken the carbolic acid applied with a view of toughening the skin. Where blebs were present these were treated to a thin coating of the pure acid, and let alone. The relief was very great It is the only treatment that I have ever used in burns and scalds."

The following is from the pen of Dr. C. J. Cleborne, Medical Director of the U. S. Naval Hospital, Chelsea, Mass. He writes:

"I believe I was the first to use carbolic acid in full strength (Merck's crystals) in buboes, boils, carbuncles, and glandular swellings generally, and can add confirmatory experience of twenty-five years to that of Dr. Gardner's. I made free openings in suppurating buboes, squeezed out the pus, applied the liquified acid to every part, dressed it with zinc ointment, and often in a fortnight the sailor was discharged to duty.

"On one occasion my apothecary on shipboard, who was greatly enthusiastic over the curative effects of carbolic acid upon buboes, injected, upon his own responsibility, nearly a drachm of the melted crystals into the urethra of a marine. *That gonorrhœa ceased then and there*, but that apothecary did not show himself to the marine for a week, for there was murder in his eye! No stricture nor other evil followed, but I should not fancy it would be the favorite injection. I have often used it as an analgesic, painting it over a felon before cutting. Dr. Ashhurst, I think, has used alcohol on cut surfaces after operations; but I think Dr. Gardner must be the first to use *carbolic alcohol*—for that is all it is—so extensively.

"Carbolic acid in a dilute form is readily absorbed. I have detected hydrochianine in the urine of women using carbolic soap in vaginal injections, the urine turning very dark in some cases; but in its full strength I do not think it is ever absorbed. I have used it in hydrocele and in cysts about the neck and jaws, and in no instance have I noticed constitutional effects. The prompt albuminizing of tissues with which the acid comes in contact renders them incapable of absorption. I regard it as the mildest and most superficial of all escharotics. I have known carbolized oil to prevent the healing of ulcers and wounds. In such instances I believe it cuts down the healthy delicate granulations, acting as an irritant. It is often useful as an application in chancroids and venereal herpes. I prefer it to the tincture of iodine as an injection into small cysts. I have injected two drachms into cysts about the jaws. In such, any excess may be slowly absorbed, but I have never known ill effects from its use."

I wish to call special attention to the use of liquid carbolic acid, full strength, or, if the crystals are used, only enough water added to make a solution, as an immediate application to all varieties of burns. Neither Dr. Brodnax nor Dr. Gardner claims originality.*

---

POTASSIUM PERMANGANATE, AN ANTIDOTE TO MORPHINE, is the burden of Dr. William Moor's report to the German Clinic, New York. He demonstrated his faith by taking three grains of morphine and immediately swallowing a solution of four grains of permanganate of potassium in four ounces of water. No effects of the morphine could be discovered. The antidotal property of permanganate of potassium for morphine, snake poison, etc., has long been known. Condy's fluid, a solution of permanganate of potassium was recommended years ago for these conditions. Dr. Moor's experiments have been tried in Chicago; unfortunately the dog which was the subject, refused to become affected, even after the hypodermic injection of six grains of morphine but continued lively and frisky, until the patience of the investigators was exhausted.

# TRANSLATIONS.*

## THE TREATMENT OF CHRONIC CONTRACTIONS OF THE KNEE AND HIP-JOINT BY TENOTOMY OF THE TENDON OR MUSCLES.

The author, J. Wahncau, reports eight cases treated by him, in which the contractions were due, respectively, to articular rheumatism, disseminated cerebro-spinal-sclerosis, infantile paralysis, spinal origin muscular atrophy, acute poliomyelitis, and traumatic inflammation of the knee-joint. In chronic cases of extensive myopathic contractions, in which the extension apparatus, or all other local treatment remain unsuccessful, Schede has practiced a free transverse separation of the shortened soft parts, his method being as follows:

For instance, in a case of shortening of the lower extremity, he makes a longitudinal incision on one side of the tendon of the biceps, the other, along the tendon of the semi-membranossus and semi-tendinosus at the point where they seem most tense in the popliteal space, of about seven or eight centimetres. All the tense soft parts between these two incisions, minus the large blood vessels and nerves, are then divided transversely, and the knee stretched, the wound dressed antiseptically and kept moist, which usually heals in the space of three to four weeks.

The author emphasizes the importance of moist dressing in wounds of tendons, this affording the most favorable means for repairing defects in such structures. In all the above mentioned cases, of which the author gives a detailed account, the results were all that could be wished. In three cases tenotomy was performed at five different places, the results being perfect. —*Centralb. für Chirur.*, 1894. —W.

## STRUCTURAL CHANGES IN THE KIDNEY FOLLOWING NEPHROTOMY.

Dr. A. Barth reports (*Archiv. f. Klinisch. Chirurg.* Bd., 46, Heft II., p. 418) the case of a woman, æt. 31, who was presumably suffering from tubercular disease of the right kidney. Exploratory nephrotomy was performed September 14, 1892. The expected changes in the pelvis or parenchyma of the kidney were, however, not found, the incision in the kidney was closed as also the external wound. There was continued rise in temperature, accompanied with violent pains in the region of the right kidney; the urine contained bacilli of tuberculosis. Thirty-four days after the first operation, October 18, 1892, the right kidney was extirpated; it was deeply imbedded in hard callous-like tissue. The microscope showed a thin cicatricial line extending into the hilus, where the incision had been made. In the centre of the kidney close to the cicatricial line, a wedge-shaped necrotic deposit was seen, and on the opposite side of this line a narrow zone of absolutely dead tissue could be defined.

On the line of demarcation between the living and dead tissues there was a distinct line of interstitial growth.

The larger necrosed portion, almost triangular in shape, still retained many of its canals and cells apparently intact, but not susceptible to coloring matter; in the outer zone the parenchyma was dead. The stroma and cells were surrounded by a fatty detritus. The cells were leucocytes, undergoing retrograde changes, some seemed filled with fatty globules. Isolated leucocytes were found in the uriniferous tubules and the glomeruli. A third zone consisting of an increase in connective tissue formation, in which there was also destruction of the canals and glomeruli, either homogeneous or granular. Here could be seen columns of cells seemingly connected with the uriniferous tubules, and suggesting the formation of new canals. Some of the destroyed tubules and glomeruli had retained their outer

* Translated for THE MEDICAL AND SURGICAL REPORTER by the translators W. A. N. Dorland, M. D., M. B. Werner, M. D., and F. H. Pritchard, M. D.

form, but seemed filled with fine tissue, not unlike connective tissue.

In the center of the wedge-shaped necrotic deposit, the vessels and canals were filled with a fine fibrinous network. Some isolated crystals of haematoidin were found in the destroyed blood-vessels.

The author justly calls attention to the similarity between this picture and cases of infarction due to emboli. The cases are the same with one exception, that in his case it was due to an injury of the artery, instead of an embolus.

In spite of this experience, the author still insists that the incision made by him is the best, since all others will lead to still greater destruction of blood vessels.

—W.

## TUBERCULAR PLACENTA.

Lehman demonstrated at the Berliner Medizinische Gesellschaft (Berl. Medical Society) a placenta, which showed tuberculous changes in the villi of the chorion. The deposit was of gray, partially yellow color, transparent, round and contained tubercle bacilli.

The patient was highly tubercular, and gave birth to a child, which died on the tenth day without showing any symptoms of tuberculosis. This may prove a solution of the question as to infection of the fœtus.—*Deutsche Medizinische Wochenschrift.* —M.

## ŒDEMATOUS SWELLING OF THE PREPUCE ACCOMPANYING THE USE OF ANTIPYRINE.

Dr. Freudenburg reports: Male, thirty years old, took seven-and-half grains antipyrine for headache. No relief; an hour later felt a burning sensation in the urethra and considerable itching of the prepuce, and behind the scrotum. Considerable swelling of the prepuce and the glans were noticeable.

Freudenburg administered the same patient some four weeks later and again gave seven-and-a-half grains antipyrine to verify the supposed effect of this drug. Two hours later, the same symptoms as stated were observed.—*Centralblatt fuer Klinische Medigin.*

—M.

## GANGRENE OF PENIS FOLLOWING INFLUENZA.

Dr. Devriant observed a case of influenza, which developed gangrena penis on the fourth day of the disease. Patient, forty-one years, had a very severe attack of influenza. On the second day he noticed a redness and swelling of penis. On the third and fourth day buboes were developed. Patient denied positively venereal infection or traumatism. Neither gonorrhœa nor chancre present. Urine was clear, no albumen or sugar being present.

The treatment consisted of elevation and leadwater solutions for the pain.

On the fourth day a large gangrenous bulla developed on the point of the glans, which extended in a few hours over one third of the penis. On the following day (fifth) the gangrenous mass was removed. This mass extended to the fibrinous sheath of the corpora cavernosa. The urethra was healthy, the veins in the gangrenous mass were filled with thrombi. Thorough removal of the gangrenous portions and antiseptic dressings cured the patient in eight weeks.—*St. Petersburger Med. Wochenschrift.* —M.

## THERAPEUTICAL SUGGESTIONS FROM FOREIGN JOURNALS.

### INALTERABLE FOWLER'S SOLUTION.

Dr. Brautigam (*La France Medcal* , No. 2, 1893) proposes the adoption of Traube's formula in the preparation of Fowler's solution. It yields an unalterable preparation. One gram (fifteen grains) of arsenious acid is dissolved, by boiling, in five c. c. (℥j¼) of caustic potash, the solution is then diluted by adding thirty grams (℥j) of water, forty grams (℥j¼) of alcohol and five to ten grams(℥j¼—℥ijss.) of essence of peppermint. Finally, enough alcohol is added to make 100 gms. (℥iijss.) The dose is from ten to fifteen drops in twenty four hours.

### STATIC ELECTRICITY IN CHOREA.

Dr. R. Verhoogen (*Revue Internationale de Biblographie*, No. 22, 1893) reading the results which Dr. Courjon of Lyons, had obtained with static electricity in the treatment of two cases of chorea, in children where the disease had but recently appeared and where the writer had obtained almost immediate and lasting results, determined to try it. He had under his observation two typical cases, and, from his results he can completely confirm Courjon's recommendation. It succeeded where the usual means of treatment failed, and though the number of patients treated was small, he thinks it deserving attention.

### STRYCHNINE IN SNAKE BITES.

Dr. Smith (*Australasian Medical Gazette*, No. 11, 1893) reports the case of a boy ten-and-half years, who being bitten by an extremely venomous serpent, was cured by subcutaneous injections of strychnine, even after bloody vomiting, a semi-comatose state following convulsions, collapse and small pulse announced approaching death. The effect of the injections was immediate, for the next day he was up and about and able to work.

### GRINDELIA ROBUSTA.

Dr. Jasiewicz (*Le Mercredi Medical*, No. 49, 1893) states that this drug is easily taken in any preparation and it may be prescribed in elevated doses, yet it is best to give it in broken doses, on account of its slight toxicity. A very large dose at one time might be fatal. It causes a mild sensation of warmth in the stomach, slows the respiratory and cardiac movements, dilates the pupils and induces sleep. It has a slightly acrid and pungent taste. It is especially indicated in respiratory neuroses, asthma, especially the spasmodic form, whooping cough and similar coughs, nervous cough, hay fever and emphysema. It acts favorably in acute bronchitis, but it must be taken for considerable time. In chronic bronchitis it is less satisfactory. In whooping cough antipyrine acts better as a sedative though grindelia may be administered, on the contrary, much longer, without fear of unfavorable consequences—a considerable feature in a disease requiring so long treatment. Though it decreases the violence of the cough it does not shorten the duration of the disease, for this disease is not a respiratory neurosis but an infectious disease, requiring antiseptics, antispasmodics and tonics.

In asthma it is more active. It calms the dyspnœa, prevents its return, but does not ultimately remove the disease. Here the iodide of potash is most efficacious in this latter respect. It is a precious remedy in spasm and has been found of value in stridulous laryngitis. Externally, Dr. Bardet has found it of service in vaginitis, genito-urinary catarrhs and burns. Dr. Bocquoillon recommends it in the itching of skin diseases. There is a certain resemblance, therapeutically, between it and belladonna.

### SULPHIDE OF SODA IN LEAD POISONING.

Drs. Peyraud and Quinquad (*Le Mercredi Medical*, No. 49, 1893) have experimented on animals and persons, poisoned by lead, in order to determine the best means of assisting the elimination of lead from the organism. The good effects of the chloride of soda were already well known to them and they can confirm this action from their experiments but they find the sulphate to exercise a still more energetic influence. It acts the same upon mercury as lead.

### RHEUMATISM IN CHILDREN, AND ITS TREATMENT.

Prof. Jules Simon (*Le Bulletin Medical*, No. 97, 1893) states that in children it chiefly appears between five and thirteen

years, and contrary to what he observed in adults, attacks only one joint. The swelling is more pronounced and not only the synovial membrane but all the tissues around the joint are inflamed. The fever is generally only moderate and rarely reaches the height that is seen in adults. In the morning, sometimes it falls one to two, or even two and a half degrees. Endocarditis and pericarditis are observed more frequently than in adults but do not assume the dangerous character; often lasting two or three days, and even if peristing for some time rarely being followed by the consequences seen in later life. In children compensation is much easier. It rarely becomes chronic. Muscular rheumatism in children chiefly affects the sterno-mastoid muscle and the contiguous parts, often simulating an attack of tonsillitis, and is mostly associated with inflammation of the atlanto-occipital articulation, which is characteristic of youthful age. Yet other regions as the upper arm, thigh and buttocks may also participate. In acute articular rheumatism, rest in bed is above all things indicated, then warm aromatic beverages and milk. To the affected joint and its surrounding region, the following liniment may be carefully applied:

| | | |
|---|---|---|
| Extract of bellandonna..... | 2 gms. | (grs. xxx.) |
| Oil of hyoscyamus..... | 15 " | (3iv.) |
| Oil of chamomile..... | 30 " | (3j.) |

Over this apply a layer of cotton batten, so that the joint is in a permanent sweat bath. Internally, the best remedy is the salicylate of soda, but if it is not tolerated, try the sulphate of quinine. Do not begin immediately with large doses. The first day one may prescribe seven and a half grains, the next day twenty-two grains and so on up to forty-five, or at the most fifty grains. On the second day after the maximal dose, gradually decrease to a daily dose of twenty-two grains. Even after recovery—in children it lasts, as a rule, fourteen days—continue the drug for eight to ten days at twenty-two grains per diem. If the disease becomes chronic, employ massage and electricity, the constant and weak current. Internally, together with tonics, one should employ the tincture or some other preparation of colchicum, which is of great service in the chronic form. For eight days, give ten drops of the tincture, before going to bed, then discontinue it for eight days and so on to complete recovery. In the intervals, one may use the iodide of potash, which, of itself, is not as active as colchicum. He warns especially against sending such children to the sea-shore or damp regions.

---

### SALT WATER IN ACUTE ANEMIA.

Dr. Ostermann (*Muenchener Medicinische Wochenschrift*, No. 2, 1894) reports that in Martin's Private Hospital, in Berlin, he has obtained very favorable results with infusions of salt water in acute anemia. Hypodermic injection is especially recomended. The needle is introduced into the subcutaneous tissue in the vicinity of the mammary gland or in the intraclavicular region, the water allowed to flow in from an ordinary irrigator, with continuous massage in the direction of the needle. In this way one may inject in a few minutes from two to three hundred grams (six to ten ounces) and repeat the injection, in a short time, if necessary. At the same time one should employ stimulants, ether, musk or camphor, subcutaneously.

If the heart be especially weak, one may aid it with artificial respiration. The solution is to be injected, prophylactically, in every anemic person where an operation is necessary and, obstetrically, in placenta previa.

---

### FREQUENTLY RECURRING EPISTAXIS.

Prof. Cozzolino (*Bulletin Medical*, No. 101, 1893) rejects the use of the perchloride of iron and advises the employment of a solution of trichloracetic acid, in distilled water; 1 gm.: 30–40 gms. of distilled water. A tuft of cotton is wound around a splinter of wood and the solution applied directly to the cartilaginous septum whence the hemorrhage generally comes. In order to prevent the disagreeable sensation of burning, one may add a little cocaine or better tropacocaine. The remedy acts rapidly, a scab forms on the cauterized spot which falls off and the wound heals.

---

### GARGLE FOR SIMPLE TONSILLITIS.

In *Revista Clinica Terapeutica*, (No. 12, 1893) the following formula is recommended in simple tonsillitis:

℞

| | |
|---|---|
| Borax, | 6gms. (3iss). |
| Tinct. of Benxoin, | 15gms. (3iv). |
| Rose Water, | ad 130gms (3vss). |

Gargle frequently with this mixture.

# BACTERIOLOGICAL NOTES.

## STREPTOCOCCUS IN PERNICIOUS ANÆMIA.

An interesting case of pernicious anæmia and its causes is reported by Fischel and Adler (*Zeitschrift f. Heilkunde*, No. 4, 1893). A patient who had contracted a slight wound in the left heel some months previous to the examination was admitted to treatment on account of anæmia. The blood corpuscles were abnormal in number and other symptoms were present which led to the diagnosis of pernicious anæmia which resulted in death. An hour before death the blood for the first time was examined for bacteria and chains of streptococcus were discovered. A few minutes after death cultures were made from the blood. The *post mortem* examination confirmed the orginal diagnosis. The cultures developed streptococci which resembled *streptococcus pyogenes* very closely, It was pathogenic for mice. The author thinks that the anæmia was the result of the streptococcus which gained entrance at the time of injury of the foot and which had developed a chronic case of septicæmia. The argument is that the toxic products of the germ causes a deterioration of the blood which enables the streptococcus to enter the circulation and produce the somewhat rapid fatal results. To support this view they experimented with sterilized cultures of the streptococcus on rabbits which resulted in the diminuted red and white corpuscles and, finally death, of the animals. The author lay much stress upon the importance of bacteriological examination of the blood early in the course of such of troubles. They also point out the difference in the nature of the disease which they studied, the deterioration of the blood corpuscles, and the septicæmia usually produced by these bacteria.

## THE ETIOLOGY OF PERITONITIS FROM PERFORATION.

The exciting cause of peritonitis even when induced by perforation of the intestine has been attributed to many causes, but the doubt that is entertained concerning the exact factors gives the results of certain definite investigations of the subject considerable interest. Barbacci (*Centralblatt f. Allgem. Path.*, Bd. IV., No. 19) gives the results of his study of fourteen cases of peritonitis produced by perforation. In addition to these cases he has made several experiments on animals. The conclusions which he has reached are of special interest. They are as follows:

1. Cultures made from the peritoneal exudate in cases of peritonitis from perforation in man, develops usually only a single species of bacteria—*bacillus coli communis*. Occasionally, however, diplococcus lanceolatus capsulatus (Frænkel) can be shown to exist in the exudate by the inoculation of mice and rabbits.

2. By artificial perforation of the intestine in the dog an affection precisely similar to that following the perforation in man may be induced.

3. In both man and dog only one organism, *bacillus coli*, is found in cultures from the peritoneal exudate although the latter may be found to contain very varied organisms.

4. After the entrance of the fæcal matter into the peritoneal cavity, the various bacteria therein contained develop equally with *bacillus coli* during the early stages of the inflammation which is induced. But subsequently they die, whereas *bacillus coli* continues to thrive and thus is susceptable of further cultivation.

5. No efficient cause for the death of microbes can be assigned. Experiments do not support the theory that they succumb to *bacillus coli* in the struggle for existence.

6. In a number of cases one finds bacillus coli in the heart blood of persons who have died of perforation peritonitis. In others it is not to be found there; and this, coupled with the fact that it is absent from the blood of the dog when the necropsy is performed shortly after death, renders it probable that, in the first men-

tioned cases, the entrance into the blood stream took place *post-mortem*.

7. The diplococcus lanc-capsulatus is never found in the exudate in cases of the dog, and as it is also absent in many of the human cases, one may conclude that this organism does not play an important part in the pathogenesis of the perforation peritonitis.

8. As regards the course and termination of the disorder much depends upon the amount of time which has elapsed since the preparation. If the aperture of communication can be closed inflammation of the peritoneum may be checked, even though far advanced, and complete recovery will then be secured.

10. The intestinal gases which pass into the peritoneal cavity with the feces play a not inconsiderable part in orginating and perpetuating the peritoneal inflammations.

11. The latter is due to two co-operating causes, each of which is by itself self imperative, namely, its extravasation of feces and of gas and the development of the germs contained in the former. The inflammation is perpetuated by the continuous irritation of the extravasated matter.

12. Death in cases of peritonitis from perforation is due to an intense intoxication of the organism that results from absorption of the fluid and gaseous contents of the bowel and the toxic bacterial secretions.

## DIPHTHERIA.

The importance of pseudo-diphtheria bacillus, its relations to the Klebs-Loeffler bacillus, and the efficiency of antiseptic treatment of diphtheria have all been matters of careful investigation, and still remain questions of interest. Kossel, *Deutsch Med. Wochenschrift*, No. 46, 1893) has brought together the results of certain recent investigations in these lines which are quite interesting. It is now generally considered that the pseudo-diphtheria bacillus is only an attenuated form of Loeffler's bacillus, and that it may regain its virulence. The virulence of the diphtheria bacillus depends on the alkaline reaction of the boullion in which it is cultivated, on the age of the culture, on the size of the animal, and on the place of injection. The production of the diphtheria poison dependent at first only on the original virulence of the culture and the alkalinity of the medium in which it is cultivated. Oertel differentiates two kinds of membrane: (1) small greyish, white or yellow points of of deposit, which later become confluent and spread to adjacent parts; and (2) in addition to (1) an œdematous swelling of a tissue, which is dull in appearance and remains smooth. This dullness extends into the deeper parts, and the epithelium, also assumes an opaque color. When this is detached it bleeds, this is malignant diphtheria. Leucocytes may accumulate in the deeper layers of the tissue and produce necrotic areas which may ultimately rupture on the surface.

*Treatment:* Antiseptics are applied in the first case in the form of spray (2 to 6 per cent carbolic acid) every two hours. In the latter case caustics should be avoided. Decomposition of the membrane should be guarded against. The surface should be swabbed with carbolic solution after the removal of the membrane. The internal use of potassic chlorate is not recommended, but mercurial salts may be tried.

Klebs has endeavorod to find a specific treatment (*British Medical Journal*, 1893, p. 1070, Nov.) but Kossel thinks that in the absence of bacteriological proof some of his cases might not have been true diphtheria. Klebs answers this, and states that they were genuine cases and adds that he has since treated forty new cases with only four deaths.

[Some time ago Dr. Robert Reyburn, of Washington, D. C., published an article in the *Medical Record*, in which he reported several cases of successful treatment of diphtheria by the use, locally, of a strong solution of mercuric chlorid. He used as high as 1 to 500 solution. His cases, were in part, demonstrated diphtheria, as the Klebs-Loeffler bacillus was found in the membrane. He administered mercury salts as well as applying it locally, but he attributed his success to the antiseptic treatment.—*Ed.*]

RODERIC C. PENFIELD
Publisher

147-149-151 North Tenth Street, Philadelphia

TERMS:—Three Dollars a year, strictly in advance. Sent four months on trial for $1.00.

REMITTANCES should be made payable only to the Publisher, and should be made by Postal Note, Money Order or Registered Letter.

NOTICE TO CONTRIBUTORS:—We are always glad to receive articles of value to the profession, and when used they will be paid for, or reprints supplied, as the author may elect. Where reprints are desired, writers are requested to make a note of that fact on the first page of the MS. It is well for contributors to enclose stamps for postage, that the articles may be returned if not found available.

SATURDAY, MARC 10, 1894.

## EDITORIAL.

### THE EFFECT UPON THE NURSLING OF THE MOTHER'S DIET.

The feeding of infants on artificial foods is a growing evil for which, although they inveigh against it, physicians are in a large degree responsible. Efforts are made to explain the evil away on such grounds as the desire of the mother to avoid the inconveniences of her natural duties, or of changed conditions of life causing inability to furnish food in sufficient quantity, if at all, or of deficient quality of the mother's milk, or other conditions, for all of which the mother is responsible. These conditions do exist in a greater or less degree, but aside from actual and acute disease, the maternal conditions may be tersely summed up in the statement that the mother is unwilling to make the sacrifices necessary if she performs her duty to her child. The responsibility of physicians lies in weakly conceding to the patient's desires, in place of strenuously insisting upon the mother's every effort to carry out the provisions of nature.

In these days of milk-foods, prepared foods, substitutes for mother's milk, etc., etc., mothers do not understand that the nature which provides organs for bearing children, also provides organs for nursing children, and intends that these organs should be for use rather than ornament. She does not realize that the products of modern science at best, are but poor substitutes for the products of nature. If the physician would insist upon the mother performing her natural functions despite her assertions that she 'cannot nurse the child,' 'never could nurse her children,' 'didn't have milk enough,' 'nipples too small or too tender,' or 'milk left her in two or three months,' etc.—if the physician should insist, and the mother persist, both would be surprised to find that long abused nature would still be willing to do her proper work.

Patient endurance of discomfort, persistent effort and proper food will eventually demonstrate the ability to nurse their infants, in nine out of every ten mothers who assert the necessity, in their individual cases, for "bringing up the baby on the bottle." And that, too, without scouring

materia medica for imaginary galactagogues, and likewise to the very great benefit of both mother and infant.

During his six years' service at the Preston Retreat, Dr. Joseph Price gave the medical profession, through that institution, some most valuable object lessons in obstetrical science.

There was no secret in the methods used to make that institution the model maternity of the world so far as professional results are concerned. His guiding principles were *care*, *cleanness*, and *common sense*. The strictest supervision of every detail, scrupulous practical cleanness and not so much of theoretical cleanliness, and simplicity in all matters, enabled him to complete his service with a mortality record never equalled in private or public maternity work.

It was a law with him "to allow the mother to bear her own children," and it was equally the rule to require each mother to nurse her own infant during her stay in the institution. So very rare were exceptions to this rule necessary, that a nursing bottle could not be found in the entire institution. The patients in the Retreat were in no respect an exceptional class, save in the fact that so large a proportion of them were ill-nourished and impoverished in physical health when they entered the hospital — conditions which would entitle them to claim inability to nurse infants. Another fact of interest was noted, namely, that many mothers, who while in the house furnished abundant food supply and left the institution with thriving babies, would, after leaving, put the baby on the bottle as a matter of personal convenience, and in a surprising proportion of such cases, would lose the babies within a few months.

The moral to be drawn is that almost every woman who can bear a child can nourish it. Attention to the body functions, generous supply of simple, nourishing food, and early and persistent efforts to establish and develop the mammary secretions were the only methods used to secure these results.

In general practice the physician is too apt to give up the contest too early or to rely upon some form of stimulant to the glands, which eventually proves delusive if not injurious. It is a common practice to administer alcoholic beverages in the form either of ale, beer, or porter to nursing women for the purpose of increasing the milk supply. Beyond question these articles are capable of doing much injury to both mother and child, and their indiscriminate employment for such purposes should be interdicted.

Dr. J. W. Byers, in the *Annals of Gynecology and Pediatry*, has made some very pertinent remarks on this subject. He says: "The truth is, in this practice of using alcoholic drinks the profession has followed the customs and whims of the laity, rather than the usual process of instructing and leading the latter. That there are conditions and circumstances in which the administration of malt liquors is of decided benefit to both mother and child, no one will undertake to gainsay. But that they are indicated in every instance of deficient lacteal secretion, or that the exigencies of the case ever render necessary their use to the extent as is commonly employed, none can maintain or justify. The promiscuous and general practice of using malt liquors by nursing women is irrational, does a vast amount of harm, and often causes disease in the suckling. We know that the mammary gland, for all practical purposes, may be considered as an organ possessing functions of a twofold or mixed character, namely, secretion and excretion. Under normal physiological conditions the first of these processes is in almost exclusive operation, though, is shown by experiences, the slightest alteration in the condition of the organism, whether of an emotional, medi-

cal, or dietetic character, may so change this secretion that it becomes to all purposes and effects an excretion, and an innocuous, healthy pabulum for the child is converted into a deleterious or poisonous substance."

"Experience is very general in showing that the milk fats and albumins, in increased proportions, have a decidedly injurious effect upon the digestion of the infant when taken into the stomach in excessive quantities. From a number of experiments conducted by Zaleski he found these substances in the milk in excessive proportions whenever the mother had partaken of alcohol. In each case where the mother was tested with malt liquors, the fat and albumen appeared and caused more or less disorder and distress of the digestive apparatus of the suckling. These deleterious influences, however, were not the worst. Analysis of the milk further revealed the fact that it actually contained alcohol and the micro-organisms peculiar to malt liquors; that the liquor drank by the mother actually passed out *in toto* through the mammary gland and on into the child's stomach, and there produced all the phenomena incident to digestive disorders and febrilê disturbances. These facts point to the belief, and support the attitude, that the mammary gland under certain conditions exercises the function of an excretory organ, and that under some circumstances it becomes nothing more than a filter through which the food and drink taken by the mother, passes directly into the stomach of the child. This being true, we are in a position to understand and appreciate the importance of the relation of the diet of the mother and the well being of the child. When we prescribe alcohol for the mother, we at the same time do so for the child."

"The diet of the mother is a stage in the milk-producing process, and the milk she produces, is, in every instance, the result, and only the result, of the food of which she partakes. If it be improper, unsuitable, or contaminated, the milk will express this in a proper ratio. In the case that beer or ale is administered it will find this outlet, and while it does not evidence deleterious influences to the extent of producing the worst results in the form of either colic, indigestion, or diarrhœa, in every instance its effects are present, and these are always among the possible results of its use. The effects of fat and albumin, when present in breast milk in excessive proportions, in producing evil effects on the child are too well recognized to dwell upon. That the more severe of stomach disorders, gastro-intestinal catarrh, enteritis, or even cholera infantum, are due to these substances, as a result of the abuse of malt liquors in the mother, is certain, though such is not generally admitted or recognized."

"Take care not to advise a woman, whose milk supply is reasonably full, to resort to beer or other liquors in order to increase it. Always impress upon them the increased risk to the child incurred by using them."

---

**Change of Meeting Place.**

In view of the fact that the largest and best hotel in Gettysburg was burned a short time ago and will not be rebuilt in time for the meeting of this Society, it was deemed best after consultation with the Board of Trustees to change the place of meeting; and as the Philadelphia County Medical Society extended an invitation for this Society to meet in Philadelphia, this was accepted.

The Medical Society of the State of Pennsylvania will, therefore, hold its Forty-fourth Session in Philadelphia, May 15, 16, 17, and 18, 1894.

H. G. McCormick, *President.*

Wm. B. Atkinson, *Secretary.*

# ABSTRACTS.

## IMPERFORATE ANUS, WITH RECTO-VAGINAL FISTULA IN A PATIENT NINTEEN YEARS OF AGE.

Mr. Henry Thompson reports a case of a patient, who was sent to the Hull Infirmary on September 25th, 1893. The mother stated that the girl was a week old before the nurse found out that there was any malformation. When five or six weeks old, Mr. Thompson, of Beverly, "tried to make a proper opening," but failed to do so. When fourteen months old she was brought to the Hull Infirmary and examined. Nothing was done, but the mother was advised to bring her again when fourteen or fifteen years old. During the whole of her life of ninteen years, the girl has never had control over defecation, but during childhood she had relief without the administration of an aperient, although the mother stated that up to admission to the Hull Infirmary she had never known her to pass a "formed" motion. Seven or eight years ago she began to suffer from attacks of "sickness and purging." At first these attacks only occurred at intervals of three or four months, but latterly there had been only, as a rule, an interval of a month or so.

During these attacks she had stercoraceous vomiting and constant passage of fluid motions. The patient had never menstruated, but had always been an active intelligent girl. On admission to the hospital she appeared more like thirteen instead of ninteen years; there was an absence of an anus, its site was marked by a cicatrix.

The hymen was absent, the vagina capacious. Just within the vagina on its posterior surface, a round aperture could be felt communicating with the rectum, which was felt to be loaded with a huge accummulation of fæces, which probably extended through the whole of the large intestine. On October 7th, the patient was anæsthetised, the lower bowel cleared, and the following operation performed: A combination of Mr. Whitehead's for severe hemorrhoids and Lawson Tait's splitting oporation for ruptured perineum. The rectum being plugged through the vaginal fistula. A verticle incision was made from the apex of the perineum to the tip of the coccyx and continued down to, but not at first dividing, the mucus membrane of the rectum. The rectum was then freed for some distance from its attachments so that it bulged into the upper part of the wound like the end of a sausage. Anteriorly each side of the vaginal fistula was split and the posterior wall of the vagina was dissected up from the anterior wall of the rectum for some distance beyond the upper end of the fistula.

After continuing the original vertical incision through the mucous membrane of the lower end of the rectum seven sutures were inserted, attaching the edges of the edges of the freed rectum to the edges of the skin, so as to form an anus. These were not tied until the vagiual fistula had been sutured. Commencing at the apex of the vaginal fistula, a small threaded, right-angled needle was passed through the mucus membrane on one side from before backward, then catching the other side from behind forwards, so as to bring together the anterior one and a half inches of the fistula. A strong handled threaded curved needle was then passed, first within the split edge of the fistula on one side, and then within that of the other side. This was done in three places, and all the stitches then tied, first those of the vaginal fistula, then those around the new anus. All that remained to be done was the insertion of numerous superficial stitches in the perineum and behind the new anus. The result was good, except the difficulty in expelling the bowel contents, that power having never been developed, but abdominal massage with aperients have produced an improvement and it is probable that the muscular power will develop and she may be able to have natural evacuations without any aid. —*Lancet*, Feb., 1894, pg. 403.

[The operator is certainly to be congratulated upon the carefully studied method of operation as well as the excellent result —Ed.]

# CURRENT LITERATURE REVIEWED.

IN CHARGE OF ELLISTON J. MORRIS, M. D.

## THE ANNALS OF GYNÆCOLOGY AND PÆDIATRY.

for February. Dr. Richard C. Norris reports

**A Case of Symphysiotomy.**

The pelvic measurements of the patient were as follows:

| | |
|---|---|
| Inter-splnous | 19½ cm. |
| Inter-crestal | 20½ cm. |
| Diagonal | 19 cm. |
| Circumference | 70 cm |
| External conjugate | 16 cm. |
| Inter-trochanteric | 27 cm. |
| Diagonal conjugate | 9 cm., scant. |
| Estimated conjugate | 7 cm., scant. |

After repairing the vaginal and perineal lacerations, the index finger was inserted in the abdominal wound, and the anterior wall was pushed back as the cut surfaces of the symphysis were allowed to come together. The abdominal wound was then closed with silkworm-gut sutures, and the usual firm binder applied around the pelvis. The diameters of the child's head were as follows:

| | |
|---|---|
| Bitemporal | 8 cm. |
| Biparietal | 9¼ cm. |
| Occipito mental | 14½ cm. |
| Occipito-frontal | 12 cm. |
| Trachelobregmatic | 9¾ cm. |
| Occipito-frontal circumference | 32 cm. |

The child, a female weighed eight pounds, was still born.

The patient's convalescence was uneventful until the third day, when cystitis developed, followed by incontinence of urine, which contained an abundance of pus and numerous tube casts. The patient had been catheterized, without any special care as to chemical cleanliness, by one of the physicians who saw her before the author's visit. She also required catheterization after delivery.

The cystitis under appropriate treatment gradually improved, and at the time of discharge from the hospital there was no incontinence of urine and only a small amount of pus. On the fifteenth day the patient developed mania; beginning as a condition of mild hilarity with irrepressible loquacity. The highest temperature during her five week's stay at the hospital was 101°, the average being 99° Her weight upon leaving the hospital was seventy-six pounds; her height, five feet three inches.

The points of interest in the case are:

(1) The prolonged labor, about ninety hours, which is believed to be the longest period of labor in any case upon which symphysiotomy has been performed in America.

(2) The difficulty in accurate estimation of the conjugata vera in any case of flat pelvis, a difficulty, the author believes, more readily overcome by Hirst's modification of Skutch's pelvimeter than by any other means at our disposal.

(3) The degree of separation at the pubic joint, which was not more than one inch.

(4) The prompt appearance of cystitis following the use of an unclean catheter in a bladder which had been subjected to prolonged compression and perhaps contusion.

(5) The development of so-called puerperal insanity.

Dr. George J. Engelmann contributes a paper on

**Vaginal Hysterectomy,**

considering especially hysterectomy by morcellement and the vaginal route in certain pelvic operations in place of laparotomy or the abdominal method. In opposition to his formerly expressed opinion, he now says that in cases which can often not be completed by the laparotomy, when inflammation has preceded, when suppurative salpingo-ovaritis and peritonitis complicates the case, when extensive adhesions exist, that the vaginal operation is indicated; and in extreme cases, in purulent bilateral salpingo-ovaritis with adhesions, matting together of intestines and omentum, and multiple pus centres, the vaginal route is preferable if not imperative, and abdominal section is relegated to simple non-adherent cases, admissible in suppurative forms only if unilateral or if distinct enucleable centres exist.

The vaginal method takes the place of cœliotomy for the following operations on the pelvic viscera:

(1) Hysterectomy proper for malignant disease of the uterus, carcinomatous, sarcomatous, or adenomatous; for benign tumors, fibromata and myomata, not extending above the navel; painful metritis or hemorrhagic endometritis resisting treatment; for otherwise ungovernable cases of prolapse or inversion. These are now generally-accepted operations. The novel features are:

(2) Hysterectomy for bilateral suppurative disease of the appendages, with accompanying disease of the uterus.

(3) All forms of pelvic suppuration and inflammatory deposits.

(4) Removal of the diseased appendages of one side only.

(5) For minor operations, the breaking up of adhesions, replacing and fixation of the uterus, and for purposes of examination.

The advantages of the vaginal route for all pelvic operations to which it is applicable are: the proximity of the parts to the hand of the operator; the possibility of controlling the work of knife and scissors by the eye; the rapidity of operation, which is made by the absence of ligature or suture; the absence of hemorrhage by the application of forci-pressure before section; the avoidance of the peritoneal cavity proper to a more or less marked extent. To this he mainly attributes the absence from shock which is claimed for these operations. No visible cicatrix is left, and the possibity of ventral hernia, which is not infrequent after the abdominal operation, is avoided. Injuries to the viscera can be as readily remedied as during operation by the abdominal incision, but they rarely occur, as the intestines are not likely to come into view.

The one objection is the necessarily small field of operation, the smallness of the opening, which would limit the opportunities for this method were it not for the possibility of *morcellement*, which admits of the successful removal of large fibroid tumors extending as high as the umbilicus, or of fibroid tumors and inflammatory masses almost filling the pelvic cavity.

The vaginal operation appears to the author as the operation of choice in cases of extensive inflammation and suppuration, and whenever practicable it should be resorted to, by reason of its simplicity and rapidity and on account of the avoidance of the abdominal cavity. The very adhesions which form an obstruction in our efforts to reach the pelvic viscera by abdominal incision, the matting together of intestines and omentum, are a protecting guard against that dangerous cavity in operations by the vaginal route.

Hysterectomy by *morcellement* also affords a far greater probability for a cure for pyosalpinx of gonorrhœal origin, a cure which would appear probable or possible only by this method of operation, because it admits of, if it does not necessitate, the removal of the uterus as well, and he believes that removal of that organ in these cases is a necessity, that the imperfect results which accompany so many of the so-called successful operations for pyosalpinx and pelvic suppuration by the abdominal incision are due to the leaving of the uterine body; within the uterine mucosa and the remnants of the tubes is left the nidus of disease, and a cure, a restoration to health by the mere removal of the larger pus centres is improbable.

The method of performing the operation, its technique, the instruments required and the after treatment of the patient are all described by the author.

Dr. Charles P. Noble discusses

**Procidentia Uteri.**

Among the causes of the condition he gives tight lacing, from its interference with the proper position and motion of the viscera; the loss of pelvic adipose tissue from some sudden wasting disease or at the time of the menopause. Retro-displacement of the uterus and increase in its size and weight are also given as causes, though in his experience by far the most common is laceration of the pelvic floor, especially lacerations involving the levator ani muscle and pelvic fascia. In regard to the treatment, he advises immediate restoration of a torn perineum following labor. He believes that the practice of putting in two or three sutures from the skin perineum cannot be too strongly condemned, because all severe lacerations extend two or three inches up one or both sulci of the vagina, and cannot be reached by sutures introduced from the skin perineum.

In those cases complicated by supra-vaginal elongation of the cervix he operates by doing a high amputation of the cervix, anterior colporrhaphy, and Emmet's perineorrhaphy. In operating upon the pelvic floor, the upper sutures are of catgut and the lower ones of silk, thereby obviating the necessity of removing the upper sutures, which embrace only the cut vaginal walls, and which are used only to help in narrowing the vagina. Silk is used in suturing the torn ends of the muscles and for the external sutures. The ones in the skin are removed in a week, those in the vagina after two weeks. He believes that it is wise to treat patients having procidentia for some weeks prior to their operation. The uterus should be reposited and kept in position by means of tampons.

In regard to the use of the pessary for procidentia he says: "Excepting those rare cases in which the procidentia has occurred in spite of the fact that the pelvic floor is intact, the use of the pessary for this condition is clearly illogical. A pessary can never restore a torn pelvic floor; and if this accident has been the cause of the procidentia, any treatment except the repairing of the injury is clearly illogical, and can be only of temporary value. The pessary is a useful instrument in the treatment of slight descensus and of retroflexion of the uterus when the pelvic floor is intact. The pessary should be supported from below, partly by the vagina itself and largely by the encircling slips of the levator muscle. It should never get its support from the pelvic bones, which is what happens when a large pessary is introduced to hold up a procidentia when the pelvic floor is widely torn. Used under these circumstances, a pessary must be large in order to be retained, and when it is large it invariably presses against the pubic bones. It is only necessary to point out how illogical this use of the pessary is in order that its application may be condemned."

Dr. J. T. Wilson discusses the question

**Does Gonorrhœa in the Female Invariably Prevent Conception?**

in a short but interesting paper. After reporting several cases in which the patient became pregnant atter undoubted infection he says:

"That gonorrhœa does frequently prevent conception is probably well established, but I do not think it is by any means a universal rule. Clinical illustrations are too many to the contrary.

If Nœgerrath's statements were literally true, sterile women and fruitless marriages would be far more common and the increase in the race would be greatly lessened, for these are a surprisingly large percentage of men, judging from my experience, who, if they confessed the truth, have suffered at some time in their lives with gonorrhœa."

Dr. Robert P. Harris contributes a description of "The First American Symphysiotomy," which he claims was performed by Dr. William Thomas Coggin, now of Athens, Georgia, who operated in Freedman, Northeast Alabama, on March 12, 1892, more than six months before Professor Charles Jewett, of Brooklyn. The operation was an entire success. The remaining paper in this issue is "Nephro-Lithiasis" by Dr. A. H. Cordier.

THE BROOKLYN MEDICAL JOURNAL

for March. Dr. James P. Warbasse writes on the

**Etiology of Carcinoma.**

The author does not believe in the bacterial origin of this disease, and giving the history of a number of theories of such origin, shows that the organisms found by their originators are also found in other growths, and so cannot be specific. Also, since other ptomaines give reactions in these growths, the author does not regard the poisonous watery extract "cancroin," of Adamkiewicz, as proving specific antagonism, as tuberculin does in tuberculosis.

The theory the author upholds is that for some unknown cause the epithelial cells of an organ undergo malignant change, and while still partaking of the peculiarities of form, function, etc., of the organ primarily affected, they migrate and form new malignant growths, the cells of which carry on a perverted function resembling that of the organ first diseased. In proof of this theory, the author quotes secondary post peritoneal nodules, the cells of which were similar to the cells of the liver, primarily affected, and states that the fluid exuding responded to the tests for bile; also metastatic growths in bone, presenting alveoli and colloid material, resembling the thyroid gland where the primary growth existed.

Dr. Frederic A. Cook (Surgeon to the Peary Arctic Expedition) describes

**Gynecology Among the Eskimos.**

He came in contact with a tribe of about two hundred and fifty persons, known as the Arctic Highlanders, living on the Northwestern Shore of Greenland. These are probably living farther north than any other human beings in this region, and are closely confined to the territory they occupy by the peculiar situation of the country. The temperature for nine months in the year is about 20° to 50° below zero. These people, the author states, live entirely on the flesh of animals and birds, and use no salt.

Girls are married at twelve or thirteen years of age, but do not menstruate until nineteen or twenty, and do not menstruate at all during the long arctic night, four months long in this region, and look forward to the return of sunlight and menstruation to cure any disease that may spring up at this time.

The average is three children in every family, and a woman who proves sterile may be cast off by her husband, and pass on to another, until finally the birth of a child becomes a bond of marriage. Very few, the author states, prove sterile.

When about to give birth to a child a woman is put in a stone house, or, if this be not obtainable, in a snow hut, or in summer in a skin tent, absolutely alone. She is given food enough to last two or three weeks, and she gives herself any attention she may. The cord is cut by grinding between pieces of stone, and is tied with sinews.

After the cries of the child have been heard by those outside for about a week the house is opened, and visits are received from female friends. The mother is considered unclean for some time, and men will not enter the house.

Death is a common result of this peculiar custom. Abortions are very rare, and the victim of one is an object of ridicule. Children are nursed by the mothers for five or six years. Diseases of children are few, and mortality among children is small. Measles is not a common disease, but is fatal when it appears. Rheumatism and consequent heart troubles are about all the adults suffer from.

A little farther south the unfortunate effects of civilization are seen; contact with missionaries has led to better care of mothers and children, but also to the use of civilized clothing, whiskey, coffee, tobacco, tea and sugar, all unsuited to Eskimo manners of life.

Two-thirds of these people are thought to be tuberculous, while not one case was known in the northern district, and Grippe, which was very trifling in the north, is very fatal in the southern region.

A profouse blood supply, the author says, leads to continuous bleeding from the most trifling abrasions, when white men in this region seem to have the blood driven from the surface by the cold. Another interesting pecularity is the presence of a layer of blubber beneath the skin in all parts of the body.

Pictures of animals, people, etc., shown these people were held upside down, and sketches of animals made by them were made in the same way; but those who had been among the missionaries had lost this habit. This coincides with the theory of the inverted retinal image being mentally reversed, as a result of education.

During an interesting discussion which followed, the author declared that of forty-one or forty-two women, he was able to find only two or three with thoracic respirations. Syphilis is unknown among those who have had no contact with white people, but universal among the others. Sexual intercourse seemed only to take place during the period of sunlight, as at the approach of night the people lost strength, and became chloro-anæmic, and the slightestexertion of any kind was fatigueing. This exhaustion in the absence of sunlight was felt by the exploring party also, and led to a condition of great depression.

Dr. T. S. Lawrence writes about iodide of lime as a specific in membranous croup. He distinguishes between light-colored iodide of calcium, which he had no success with, and dark iodide of lime, which he finds of great value. Ten grains of the drug are dissolved in four ounces of water, and one or two teaspoonfull given every fifteen, thirty or sixty minutes, until the cough becomes moist. He mentions quebracho as a drug that enables red-blood corpuscles to absorb more oxygen than the usual supply from a given volume of air. He used five-drop doses of the fluid extract every three hours for a child eighteen month old.

Dr. George Dederic Holston contributes an article describing

**Neurotic (Reflex) Eczema.**

The author says although this disease is unquestionably eczema (a catarrhal inflammation of the skin) yet it differs from ordinary eczema in clinical appearance, etiology and treatment.

It occurs at all ages, but is most frequent under two years of age. Location, symmetry, tendency to sudden remission or aggravation, and rebelliousness to external treatment distinguish this from ordinary eczema.

In children the most frequent sites are the face or scalp, in whole or part, the upper extremities, confined to the extensor surfaces, deltoid, etc. Individual patches are sharply defined, circular, elliptical, or ovoid; and while resembling zoster, they group at the termination or decussation of nerves, instead of along their course.

All the appearances of ordinary eczema are seen, and the patches usually show vesicles. It differs from ordinary eczema in affecting the cheeks and extremities symmetrically.

Cases are cited to show the effect of hygiene, regulation of diet, bowels, etc., also the relief of adherent prepuce, or any kind of genital irritation, and the uselessness of local treatment without this.

Nervous sedatives may be required, in some cases ergot is very useful, and often the itching is so great as to call for salicylic acid, and menthol, ichthyol, carbolic acid, etc. Counter irritation to the neck or over the spine sometimes gives a marvelously sudden remission.

# PERISCOPE.

IN CHARGE OF WM. E. PARKE, A.M., M. D.

## MEDICINE.

### Acute Tonsillitis.

Dr. C. Edwin Miles says, in the Massachusetts *Medical Journal:* "If the pultaceous deposits develop on the tonsils or fauces, I find no remedy to surpass the following:—

℞ Ol. eucalyptus glob. ..... mxv
Spt. camphor ..... ʒiss
Tinct. guaiac. ..... ʒiiiss
Glycerin ..... q. s. ad ʒj

M. Sig.: Put 20 drops on a bit of sugar and allow it to dissolve in the mouth, every hour or two."

### Irrigation of the Stomach in the Treatment of Obstinate Hiccough.

Dr. Gallant in *Med. Week.* The author describes a case of presistent hiccough in which this unpleasant symptom occured at intervals of one or two minutes and lasted for three days. During sleep no singultus occurred. Temporary relief was obtained by the administration of the hydrochlorate of cocaine gr. 1-10 every 3 hours, followed later by 1-12 gr. doses of hydrodchlorate of pilocarpine three times daily. The hiccough reappeared and was more pronounced. Suspecting it to be of gastric origin Dr. Gallant washed out the stomach; immediate relief was afforded and the spasm promptly disappeared. A second case of obstinate hiccough which resisted chloral, opiates, ether and bromides responded to catheterization of the bladder which was distended and relief temporarily obtained for about 8 hours. Lavage of the stomach caused an entire cessation of hiccough in this case also. Gastric irrigation being a simple and harmless procedure, it ought to be resorted to in every case of obstinate hiccough whether of gastric origin or due to nervous irritation. In nervous hiccough favorable effects ought to be produced by diminishing the reflex irritability of the nervous system as was shown by passing a catheter in the case above described.

### Ice in Acute Pneumonia.

Prof. Mays urges the value of this treatment. He has the chest on the front side and back of the area affected surrounded with rubber bags filled with ice. The number of these depends on the size of the area involved. They are allowed to remain until the temperature becomes nearly normal. If a new portion of the lung is involved, the ice bags are removed to this spot, and this is continued until the tendency to extension ceases. —*Philadelphia Polyclinic.*

### Antipyrin as a Hemostatic and a Antigalactagogue.

Dr. J. S. Davis depends on antipyrin as a local hemostatic. Its effects are prompt and lasting. There is no clot to interfere with primary union, and it is in every respect the ideal hemostatic. When possible the powder is sprinkled over the bleeding surfaces and covered with borated gauze. When this method cannot be pursued a fifty per-cent. solution is injected.

By giving it in doses of four grains, every two hours, the lacteal secretion will be suppressed in from two to six days without any change of diet. He has never found it necers sary to continue the treatment longer than four days.—*Medical Review.*

### Treatment of Intestinal Hemorrhage in Enteric Fever.

James W. Allen, M. B., says: The first indication is stillness on the part of the patient. Soda water and milk, sherry whey and (if the patient is very weak) a little brandy and water—all iced—may be given at reasonable intervals. Of course free stimulation is out of the question. The patient may be permitted to suck or swallow small pieces of ice. Large draughts of fluid should be

avoided. If the hemorrhage is considerable in amount the external application of cold to the abdomen is one of the first remedies which ought to be employed. This should be done with a Zeiters' apparatus, or similar arrangement, and not with heavy and leaky bags. It is better to employ the external application of cold in an intermittent than a constant manner, for example use it an hour and omit it an hour. In addition to above methods of application of cold it may sometimes be advisable to introduce pieces of ice into the rectum.

In regard to the use of drugs the author speaks of three which he has used. These are: 1. Lead and opium combined in pill; (2) Turpentine; (3) Liquid extract of ergot named in the order of their merit.

### A Word for the Sleepless.

Dr. J. E. Huxley of Maidstone, Eng., thinks he has hit upon the natural remedy for sleeplessness. It is in brief to curl under the clothes like a kitten or put the head under the wings like a hen. His detailed description of the technique is given in a letter to the *Medical Press and Circular*, when he says: This insomnia seems now to be a universal affliction. We live wrongly; sit up late and overwork the brain and thus go to bed in an excited condition. No one seems to have hit upon the natural remedy. I think I have. People take chloral and the like at their peril, and a fatal consequence not seldom ensues. It is all wrong, for you cannot control the dose required for the exact circumstances. But try natures plan instead—lower the supply of oxygen to the blood, produce a little asphyxia, limit the quantity of air to the lungs, and the heart and circulation becoming quicker, the brain loses its stimulant and sleep follows. When you find yourself in for a sleepless night, cover your head with the bedclothes and breathe and rebreathe only the respired air. Thus you may reduce the stimulating oxygen and fall asleep. There is no danger. When asleep you are sure to disturb the coverings and get as much fresh air as you require, or when once drowsiness has been produced, it is easy to go on sleeping though the air be fresh. What do the cat and dog do when they prepare to sleep? They turn round (generally three times) and lastly bury their noses in some soft hollow in their hair or fur and "off" they go. They are in no danger, although it might look as if they were from the closeness with which they imbed their noses.—*Med. Rec.*

### Calomel as an Antipyrtic.

Drs. R. J. Nunn and A. B. Simmons, of Savannah, Ga., in the paper prepared for the Section of Therapeutics (First Pan-American Medical Congress) remark: From the use of calomel in twenty-five cases of typhoid and continued fever cases we have drawn the following conclusions:

1. Calomel is a sure and safe antipyretic, reducing the temperature from two to three degrees in a few hours.
2. Small doses will prove of no avail.
3. The ingestion of large doses was followed by no untoward event, no ptyalism, no hyper-catharsis. This is contrary to the usual opinion.
4. Diarrhœa, hæmorrhage, albuminuria, tympanites have not been contra-indications to the use of the remedy.
5. The reduction of temperature occurs without cathartic action on the bowels.
6. The Calomel acts best in combination with soda, bismuth and pepsin.
7. In some instances, the remedy appeared to cut short an attack, and in others, while having no influence on its duration, it modified all symptoms, and by keeping temperature in check, aided materially in the management of the case.—*Journal American Medical Association.*

### Prevention of Boils.

Dr. Roensbach (*Munch. Med. Wochenschr.*) in order to prevent the development of crops of boils, in the back of tbe neck and nose, especially advises persistently rubbing the region attacked with some fatty substance, as cold cream, lanoline, unsalted butter or lard. Lanoline, above all is to be preferred. The development of boils is due to dryness of the skin, and by inunction of a fatty substance the dryness is removed and the penetration of micro-organisms prevented.—*Ex.*

### Chronic Bronchitis, Etc.

The following is a formula of the late Dr. William Thompson, who died several years ago, at Lazaretto, Philadelphia, of yellow fever:

℞ Fl. ext. tarax.....
Fl. ext. rhei.....
Syr. senega.....
Tinct. tolution.....ää ʒ ss.
Sod. bicarbonat.....ʒ j.

M. Dr. Thompson prescribed this for a patient who had chronic bronchitis, acid dyspepsia, etc, with good effect, in doses of one teaspoonful three or four times daily

REFRIGERANT, SEDATIVE AND EXPECTORANT.

℞ Cit. potass. liq.....ʒ iij.
Spir. nit. dulc.....ʒ iiij.
Tinct. lobelia.....ʒ ij,
Oxy. scilla.....ʒ v.
Syr. simp .....ʒ ij

M. Sig. Teaspoonfnl pro ren ata.

The above was prescribed by the late Dr. Condie. A very efficient remedy, rather in advance of its time.—*Buckley Medical Summary.*

### A New Treatment for Pertussis.

Sidney B. Straley reports the results of the use of thymus serpyllum in pertussis. He used a tincture made from the green drug. His conclusions are:

1. Thymus serpyllum is a specific for pertussis.

2. It acts in any stage of the disease.
3. It also is a nerve sedative and gastric stimulant.
4. It is necessary to use the green plant.
5. It is perfectly harmless in doses as large as a teaspoonful of the tincture for a child of eight years.
6. The action is fully established in twenty-four hours and completed in five days.
7. Lastly: indications are that there will be no recurrence subsequently, at least not more often than in cases which run the full course.—*American Doctor.*

### Tuberculosis.

℞ Iodoformi..... gr. 20-40
Ess. eucalypti... .....
Ess. terebinthinae ... ..... ....
Ess. guaiaci.....
Creasoti..... .....āā fl 3j

M. Sig. By inhalation or spray of from five drops upward.

—*Ex*

### Importance Attached to the Condition of the Tonsil.

The author calls attention to the prominence given the tonsils by the act of gagging, which forces them forward and toward the median line, cutting off the view of all that lies beyond. Moreover, the difficulty of posterior rhinoscopy and the mystery surrounding the function of the tonsil all unite to direct the physician's attention to these little bodies. The examination of the tonsils should be conducted while they are in repose, so that any changes in the adjoining tissues may be recognized and properly treated. The author shows that the symptoms usually ascribed to large tonsils may likewise be due to the other causes (adenoid disease, etc.), and he would have these eliminated before resorting to tonsillotomy.

In conclusion, he presents the following summary:

1. Because the tonsils are easier to see than the nose and post-nasal space, is no sign that they are more important than the latter.
2. Form no estimate of the size of the tonsil unless you see them in repose.
3. Always examine the back teeth and the base of the tongue.
4. In acute follicular disease of the tonsils, look for and treat disease of the other follicular tissues in the throat.
5. Nasal obstruction, cough, and impaired voice are much more likely to be due to nasal or post-nasal hypertrophy than to tonsillar hypertrophy.
6. The fact that the tonsils are enlarged or diseased should lead us to look for a possible explanation in the parts higher up.
7. Free the nose and post-nasal space in addition to, or instead of, tonsillotomy, if you wish to improve the voice and respiration.

### Jaundice.

In jaundice, due to exposure to cold, which has brought on a slight hepatic congestion, Prof. Hare says that in a large number of cases colomel given in $\frac{1}{6}$ of a grain doses until $\frac{1}{2}$ of a grain has been taken will be found to give relief.—*C. and C. Rec.*

### Cardiac Tonic.

Dr. Edward C. Mann, of Brooklyn, N. Y., in the *Physician and Surgeon* gives the following formula:

℞ Caffein. hydrochlor.,..... 3 iss.
Strychniæ sulph.,..... ..... gr j.
Ext. belladonnæ,..... gr. iss.
Fel bovis insp.,..... 3 j.
Ext. colocynth. comp.,
Ext. aloes, ..... aa gr. xxx.
Ext. taraxaci,..... gr. 45.

M. et fiant pil. No. xxx. Sig. One three times a day.

—*The Medical Bulletin.*

### Intestinal Fluxes.

Dr. J. Zach. Taylor advises:

℞ Pulv. opii,
Pulv. plumb. acetat.,
Camphor-gum..... aa gr. xxx.
Ext. capsicum fl ,..... ..... gtt. x.
Beech-wood creasote,..... gtt. v.
Alcohol, q. s. to dissolve camphor.

M. ft. pil. No. xxx.
Sig. One to six pills daily, according to urgency of case.

—*St. Louis Courier of Medicine.*

### Removal of Warts.

For the removal of warts, Dr. R. B. Morrison, of Baltimore, Md., prescribes the following:

℞ Hydrarg. bichlor.,... ..... ...gr. v.
Acid. salicyl.,.....3j.
Collodion, ..... .....3j.

He sometimes increases the bichloride of mercury to thirty grains in the same quantity of collodion, if the milder application does not answer. It is applied every day once, the upper crust of the previous application being removed before a fresh one is made. Four such applications generally softened the wart to such a degree that gentle friction removes it plainlessly, the further dressing being any simple ointment.—*Ex.*

### Tubercular Cystitis.

℞ Ext. belladonn ,
Ext. oppii,..... aa gr. $\frac{1}{6}$.
Iodoform,..... gr. $\frac{1}{4}$.
Ceræ,..... gr. xv.
Ol. theobrom.,..... gr. 45.

M. ft. suppos. No. j.

—*La. Medicine Moderne*

### Infantile Convulsions.

Infantile convulsions are treated by Dr. Jule Simon with the following:

℞ Chloral hydrat.,
Potass. bromid.,..... aa gr. xv.
Syr. codein,..... gtt. x.
Tinct. moschi,
Tinct. aconiti rad.,..... aa gtt. x.
Aq. aurant. flor ,..... ad 3ij.

M. Sig. Teaspoonful doses, or by enema if it cannot be taken by the mouth.

—*El. Sigo. Medico.*

### Constitutional Syphilis.

A mixture often ordered in constitutional syphilis by Dr. Keyes is as follows.—(*Cincinnati Lancet-Clinic*):

℞ Potass. iodid.....3ij
Ammonii carbonatis.....3ss
Tinct. cinchonae comp.....3iv
Syr. aurantii cort.....3iss
Glycerini.....3j
M Sig. A teaspoonful, well diluted, after each meal.

—*The Coll. and Clin. Record.*

### Painful Pharyngitis.

℞ Sulphate of morphine.....gr. iv
Phenic acid.....
Tannid.....āā 3ss
Glycerine.....
Water.....āā 3iv
Paint the throat two or three times daily.

—*Eng. Med. Press.*

### Cardiac Palpitations in Neurasthenics.

Th. Zerner employs the following mixture:

℞ Iron pyrophosphate.....
Zinc bromide.....āā gr. 54
Digitalin tincture.....fl 3ss
Ergotin.....3iij
Orange flower-syr.....fl 3vj
Dist. water.....fl 3iiij½
One to three teaspoonfuls daily.

—*Amer. Med. and Surg. Bulletin.*

### Myalgia

℞ Liniment chloroformi.....
Liniment aconiti.....āā fl 3iv
Tinct. opii.....fl 3iij
Liniment saponis.....ad. fl 3iv
M. Ft. liniment. Sig. To be well rubbed into the painful parts.

—*The Practitioner.*

### Irritable Cough.

℞ Acidi hydrocyanici diluti.....3iss
Morphinae acetatis.....gr. iss
Mucilaginis acaciae.....3j
Syrupi pruni Virginianae.....3iv
Aq., ad.....3vj
M. et fiat mistura. Sig. A teaspoonful to be sipped every four or six hours.

—*The Practitioner.*

WHY, OF COURSE.—*Stivitts*: "The German investigators are experts in bacillus hunting, aren't they?"

*Whiffett*: "Well, wouldn't you naturally expert a germ. man to cholera microbe?"

## SURGERY.

### New Operation for Prolapse of the Uterus

Freund (*Centralbatt fur Gyn.*) proposes simply to narrow the vagina to any desired extent by encircling it with a series of permanent sutures, which begin just below the utero-vaginal junction and are placed one after another down to the external orifice. Freund has used for the suture material, silver-wire, but Edebohls, who has tried the operation, and recommends it, (*Medical Record*) prefers to employ silkworm-gut.

### A New Treatment of Naso-Pharyngeal Catarrh.

Bates (*Med. News*) has treated with benefit more than fifty patients by syringing the lachrymal sac and nasal duct. Of the remedies used, olive oil gave the most general satisfaction. The syringe used is the ordinary eye dropper, with a tube drawn out to a fine point, bent at an angle of 60°, and about one-quarter of an inch long. It is small enough to enter the smallest punctum, and tapers so abruptly that it closes the largest punctum, preventing a return flow of the fluid.

To make the injection, the operator sits in front of the patient. Artificial light from an argand burner is reflected by the forehead-mirror on the inner side of the eye, direct illumination being less satisfactory. The operator may also stand behind the patient, who is then directed to look upward and outward. A piece of cotton about one-fourth of an inch in diameter is placed over the semilunar fold and held with the forefinger of the left hand with slight pressure against the upper punctum; this prevents the fluid from entering the eye from the punctum of the upper lid. The thumb of the left hand everts the lower lid sufficiently to expose the punctum.

The syringe, partly filled with the fluid to be injected, is lightly held by the bulb with the thumb and first two fingers of the right hand, the tip is inserted into the punctum and the syringe turned until the tip is at right angles to the margin of the lid and parallel to the conjunctival surface of the lower lid. Slight pressure is made on the bulb, and the level of the fluid in the syringe is seen to descend as the injection is being made.

Sometimes the injection is difficult, after the tip is introduced into the punctum; and, manipulation of the syringe up, down and in various directions, will be required to free the point from obstructing conjunctival fold. Nervous patients give trouble, and in such cocaine helps, but does not always relieve the difficulty.

### How to Cut Short Paroxysms of Whooping Cough and Some Neuralgias of the Trigeminal nerve.

Maegely (*Mercridi Med.*) Lift the hyoid bone and larynx by the thumbs applied under the greater cornua, the index fingers being kept on the ears and the other fingers on the neck. The duration of this procedure should be from a minute to a minute and a half. The author claims for his method certain cessation of the paroxysms of pertusses and relief in trigeminal neuralgia, hemicrania and globus hystericus. It is probably a phenomena of reflex inhibiation. Occasionally several attempts are required.

### Viburum for Treatment of Abortion.

Polak advises rest in bed. Morphine or opium per rectum and drachm doses of the fluid extract of viburum, or four-grain doses of the solid

extract in pills. Of thirty-two cases treated in this way, none resulted in miscarriage.—*New York Journal of Gynecology and Obstetrics.*

### The Treatment of Cholera.

By H. Rosahuksy, M. D. The following preparation has been used by me with great success in the beginning of cholera where there is profuse vomiting and diarrhœa. The same preparation has been highly recommended by Professor Botkin of Russia, and it is very extensively used by the Russian physicians. This preparation goes under the name of Guttae Botkina.

℞ Tr. Chinae Comp.
Anodyn Hoffmani.....ää 15.0
Acid Miur. Dil.,..... 2.5
Ol. Meuth Pip..... 0.3
Chinini Muriatici..... 2.0

M. S. Twenty drops three or four times a day during cholera.

In cholera infantum I use this preparation in divided doses and a large proportion according to the age, or in the following manner which gives excellent results.

℞ Acid Mur. Dil..... 2.0
Liquor Anod. Hoffman..... 6.0
Bismuthi Salicyl..... 6.0
Acid Carbol, (C. P.)..... 0.12
Glycerine..... 12.0
Aq. Meuthae Pip..... ad. 60.0

M. S. Teaspoonful every hour, according to age.

For choleraic diarrhœa, the following preparation is also good:

℞ Tr. Opii.....4. 0
Essentiae menthae.....
Liq. anod. Hoffmani.....ää 8. 0

M. Sig. Twenty drops four or five times a day.

—*Medical Record.*

## ARMY AND NAVY.

U. S. ARMY FROM FEBRUARY 25, 1894, TO MARCH 24, 1894.

Leave of absence for twenty days, to take effect upon the adjournment of the Eleventh International Medical Congress to be held at Rome, Italy, March 29 to April 5, 1894, is granted to Colonel Bernard J. D. Irwin; Assistant Surgeon General.

A Board of medical officers to consist of Major Joseph K. Corson, Surgeon; Major Walter Reed, Surgeon; Captain Julian M. Cabell, Assistant Surgeon, is by direction of the Secretary of War appointed to meet at the call of the President thereof, at the Army Medical Museum Building, in this city for the examination of First Lieutenant Philip G. Wales, Assistant Surgeon, to determine his fitness for promotion.

Lieutenant Wales will report in person to the President of the Board at such time as he may designate.

By direction of the President, the retirement from active service on the 25th of February, 1894, by operation of law of Captain George T. Beall, Medical Storekeeper, under the provisions of the act of Congress, approved June 30, 1882, is announced.

The leave of absence granted Captain Reuben L. Robertson, Assisstant-Surgeon, United States Army is extended one month.

Major John Brooke, Surgeon United States Army, retired from active service, February 22, 1894.

First Lieutenant Ashton B. Heyl, Assistant Surgeon, retired from duty at Fort Nichvava, Neb., ordered to Columbus Barracks, Ohio, for duty at that depot, on the arrival of Lieutenant Thomas S. Bratton, Assistant Surgeon, at Fort Niobvava, Neb.

## NEWS AND MISCELLANY.

### Acting Assistant Surgeons.

In the house of representatives, February 16, 1894, Mr. Richards introduced a bill to remove certain disabilities of the late acting assistant surgeons.

WHEREAS before, during, and since the war of eighteen hundred and sixty-one to eighteen hundred and sixty-five, but chiefly during the war, private physicians were employed as medical officers serving under the orders of their superior officers, as such, agreeably to Army regulations, in the armies of the United States, in addition to the commissioned medical staff, because the number of the latter was not sufficient for the necessities of the service. This class of officers was known officially as acting assistant surgeons, because they performed exactly the same duties, and were subject to the same control as commissioned medical officers. These acting assistant surgeons were employed under contract made in accordance with paragraph twelve hundred and sixty-eight, Revised Regulations of the United States Army, eighteen hundred and sixty-one, and paragraphs thirteen hundred and four and seventy-one, Appendix B, Revised Regulations, eighteen hundred and sixty-three, and were obliged to remain in the service of the United States for a stated time. Among these officers were many of the eminent physicians and surgeons of the United States. Some of the duties performed by acting assistant surgeons were as follows: They were in charge and command of United States military hospitals, known as general, division, field, and post hospitals: they had charge and command of United States military hospitals for the care of contagious disease; they were in command or in charge of hospital trains, hospital boats, and ambulance trains, and were excecutive officers of United States general hospitals; they acted as brigade and regimental surgeons and at least one acting assistant surgeon acted as medical director of a department for nearly a year; they were responsible for hospital funds and property, and also post funds; they served on court-martial, which the Articles of War require shall be composed of officers, and also on

boards of surveying, in camp, field, and garrison, on overland expeditions, and in Indian wars; they faced death and endured hardships like commissioned officers, and it is known that nearly one hundred and fifty died in the military service of the United States; and

WHEREAS these acting assistant surgeons were allowed fuel, rations, quarters, and transportation in kind, and to purchase rations from the commissary, and traveling expenses the same as commissioned medical officers with rank of first lieutenant and were accorded, by order of the War Department, the same protection in their position, the same respectful subordinate conduct, and the same military courtesy from enlisted men as if they were comissioned officers, because they were placed in the position of comissioned officers so far as related to their duties. Many of them were also required to wear the uniform of an assistant surgeon. Acting assistant surgeons who were disabled by reason of disease contracted or injury received in the military service have been granted pensions under a law which assimilates them to the rank of first lieutenant of the military or Marine Corps; and

WHEREAS because they were not commissioned as officers, but were employed by contract as such, they are denied admission to military organizations like the Loyal Legion and the Grand Army of the Republic; and to relieve this unjust discrimination, and to give a proper recognition to their patriotism, duties, responsibilities, services, hardships, and exposures, they ought to be entitled to receive the rank for which they are allowed pensions and which will relieve them from these disadvantages. The appended bill is offered for this purpose. It involves no expense to the United States Government and no change in the relative rank of officers of the medical corps of the United States Army who have been or are now in the service of the United States; Therefore,

*Be it enacted by the Senate and House of Representatives of the United States of America in Congress assembled*, That private physicians who were employed as medical officers in the armies of the United States for a period of not less than three months, in accordance with paragraph twelve hundred and sixty-eight of the Revised Regulations, United States Army, eighteen hundred and sixty-one, and paragraphs thirteen hundred and four and seventy-one, Appendix B, Revised Regulations, eighteen hundred and sixty-three, and who were known officially as acting assistant surgeons of the United States Army, and whose services were honorably terminated, shall be commissioned by the President of the United States as acting assistant surgeons of the United States Army; and the date of employment as acting assistant surgeons to be the date of commission and muster into service, and the date of the honorable termination of service as acting assistant surgeons to be the date of discharge or muster out of service: *Provided*, That no pay or allowance shall be made to any such acting assistant surgeon by virtue of this act; and this act shall not affect the rank, pay, or emoluments of commissioned medical officers of the United States Army.

### Cigarette Smoking.

We are glad to see a campaign inaugurated against the cigarette smoking curse; and we are pleased that the daily press is lending its assistance in educating parents to the evil of this terrible habit. It is also gratifying to find that so many clergymen, physicians and school teachers are doing good work in depicting the moral depravity and the physical degradation, that are sure to overtake the youngster who contracts and persists in the habit of cigarette smoking. We beg leave, however, to remind these workers in the good causes who are so ably and eloquently denouncing this most injurious habit, that no preacher is so eloquent and effective as he who practices what he preaches. Let the man with a cigar in his mouth (and several more in his pocket) explain to the small boy the evil consequences of smoking cigarettes, and he is likely to be met with the query—"What are you giv'n us;" the urchin cannot understand that a small cigarette can hurt a small boy if a large cigar does not hurt a large man. "Consistency thou art a jewel." "If eating meat causes my brother to offend, I will eat no meat."—*Ex.*

### The Old Story.

A correspondent of an English contemporary, writing from a small manufacturing town, says that the number of practitioners has risen there within four years from four to eight. The population in the meantime had not increased. As an evidence of how the doctors were prospering, three children of one of them were working in the factory. —*Ex.*

## ORIGINAL ARTICLES.

### PSYCHICAL EPILEPSY.

S. J. FORT, M. D., Ellicott City, Md.

The curious relationship of the convulsive disease, the faint boundary lines between what may be termed a well-marked disease and another equally as well marked; the combination of two disordered conditions in the one person; the peculiar features of Jacksonian epilepsy; *petit mal* in one patient, *haut mal* in another, and both forms in another; irregularities of symptomatology occuring among groups of accurately diagnosed forms of disease; all such eccentricities of diseased action render this group of diseases extremely interesting to the physiologist, the pathologist, and the medical man proper, as well as to the medico-legal functionary.

The etiology in so many cases is obscure. The lesions, if any, would seem to be of a nature to produce contrary symptoms. Very frequently the scalpel and the microscope fail to find sufficient pathological results. Causes operating from without produce directly opposite results in individuals apparently of the same physical equality.

A blow upon the knee of one child produces no injury beyond the subsequent bruise, in another child a destructive inflammation is lighted up and the joint is wrecked. One child falls and strikes its head, traumatic epilepsy ensues; others endure the same injury with no permanent injury resulting. A bruise in one woman's breast produces a cancerous growth on the site of the injury; other women recover from deep-seated trouble in these glands without an after-result.

One child is delivered by forceps and lives to be an idiot; hundreds of others show no signs of such manipulation at the time of their birth.

Notable examples of pre-natal impression and accidents are found among the institutions devoted to the care of the feeble minded; among the many thousands who are annually born into the world, how many there may be who have been subjected to the most severe pre-natal shocks without injury, either mental or physical?

We study the tabulated family histories of our defective charges and gravely point out the terrible ruin of mind made by alcoholism in one or both parents; a similar study of family histories of thousands of parents addicted to alcoholism would show thousands of children born with minds to all intents and purposes sound and whole.

It may be that nature works without design in these troubles, that eccentricity of action argues a departure from rule in the primary cause of disease, but it is probable that the increased knowledge and further improved methods of study and research will eventually show the physical deficiency, if that be the reason; however infinitesimal it may be, it cannot forever elude the researches of modern science.

Of interest to the political economist as well as the medical man is the close relationship of the convulsive habit to crime and criminals, especially interesting since the latest crop of perverts, whose mental and moral obliquity turn towards the destruction of human life. That this relationship exists is without doubt within the bounds of possibility. A somewhat intimate acquaintance with mental defectives has caused me to think that there is a far more intimate connection between the habitually vicious and depraved and the epileptic condition than at present insisted upon by authorities in this specialty.

The late Dr. Kerlin, whose thirty years of intelligent study of imbecility renders his writings of great value, in a paper published in 1881, describes what he terms the epileptic change in feeble-minded children, and the following case is one he presents which will sufficiently illustrate the remainder of his valuable paper:

"A girl of four, when brought under observation, had a chronic habit of biting, but no other special eccentricity. During the fourteen years of training at Elwyn, she ranked high in her school duties and became useful in household duties, but never really gave up her habit of biting; her paroxysms were always unannounced by visible prodroma; they were directed against the loved and unloved, and she was as irresponsible and helpless when snapping at her victim as the typical epileptic when he falls to the ground; her face became flushed after the act, with a wild, lost look in it, or sometimes it was as the face of a swimmer rising from the water more chilly than was anticipated when plunging into it—cold, cramped and surprised.

There were long suspensions of these attacks, like the hopeful rests of epilepsy, to be followed, like them, with disappointment in a fresh outbreak of her irresponsible ferocities."

It would seem that the above case was that of what is now known as "psychical epilepsy," or the "psychical epileptic equivalent." Dana, one of the latest writers, thus describes psychical epilepsy, a sub-division of *petit mal*, or, to more accurately place it in its proper category, a sub-symptom of the mild form.

"Sometimes," says this author, "the minor attacks are followed by outbursts of maniacal excitement or by sudden, violent automatic movements, and in these cases, the patient commits crimes of violence. This form of epilepsy may come on without a preliminary minor attack, and then it is to be considered a psychical epileptic equivalent."

As I have said, I think that such a case as Kerlin describes would fall rather under this type of epilepsy, evidently identical with the "masked epilepsy" of Esquirol, the *epilepsia larvata* of Morel, rather than to be given as the prodroma of true epilepsy proper, and I place the two following cases of my own in the same class.

The first is a girl now eighteen years of age, who came under my care five years ago. She was then a dull, stupid imbecile, utterly unused to the requirements of polite society, irresponsible to either love or fear, but with no especial history of outbreaks of violence or destructive habits. Under the softening influence of our school training, she gradually brightened, began to talk, learned to read and write, and displayed much affection towards her teacher and attendant.

One day she suddenly attacked her attendant, giving as an excuse that the attendant struck her first. When I saw her shortly after the fracas, she was a picture of sullen imbecility. Simultaneously with the explosion of muscular and nervous action, she seemed to have relapsed into the mental state of a year previous. In a week's time she was herself again, and remained so for a month or two, when she again exploded. Isolated for a time from her companions, she regained her equilibrium and was removed from our care to her house.

As soon as she got home, she had recurring fits of passion, alternating with periods of sexual excitement, finally going to bed and refusing to get up. By use of much physical force she was brought back to us, and the morning after her arrival she arose with the other patients, but seemed in a trance, refusing to talk, eating voraciously, leading an oyster-like existence.

Under active treatment, she finally regained her lost ground, but with her increased mentality came again the violent outbreaks of temper, followed by periods of depression. At no time in her history has there been any actual epileptic "fit."

Her family history is very bad. Her father is nothing more mentally, than a high-grade imbecile; her mother was an illiterate, excitable person, with an overgrown faculty for making money, who died recently of apoplexy, superinduced by overeating.

The other case is a boy nearly twenty. He had been under observation for three years. A nice, polite, clean fellow, capable of a certain amount of school education, fond of play, obliging and friendly. There was nothing in his history out of the ordinary run of congenital imbeciles. Both parents highly educated, and so far as known, no evidence of mental trouble anywhere on either side. The father lost a foot in battle, and has suffered intense neuralgia from the stump, the acme of

pain storms seeming to have been about the time the boy's mother became pregnant; this was the only symptom of nerve trouble anywhere in the history.

The boy showed signs of "backwardness" at an early age, and when about fourteen, without warning, eloped from home; he was returned by the police to a family well-nigh distracted, and further alarmed by his apparently being insensible. He recovered in a short time, and within two months ran away again; this time he was found unconscious under a tree in a park near the house. Coming to me, he became one of my most interesting cases, eagar to learn, easily controlled, and apparently trustworthy, giving no signs of any desire to elope for some time.

Looking out of a back window one afternoon during a heavy shower, to my surprise I saw this boy scudding across the field toward the woods. Immediate pursuit enabled us to corner him before he had gone very far, and he was finally located by a sort of barking noise, and evidences were plain that he had vomited freely. Brought home he was apparently unconscious, but when threatened with a douche of cold water rallied, and beyond considerable depression, was himself again.

Later on, he again ran away, this time not being captured until late in the evening; he was thoroughly exhausted by his efforts at pedestrianism, and kept his bed for a week.

That was the last time he ever essayed that eccentricity; later he developed a new phase. He was brought to me suffering from a pain he could not locate, and being sent to bed, remained there two days refusing to speak or eat. On the morning of the third day he got up with the other boys in his domitory, dressed and took his place in his class as though he had never been away.

Gradually we noticed that he was standing still mentally, the slightest rebuff or reproof or obstacle to his desires brought on a paroxysm of this alleged and exceedingly elusive pain, to be followed by a period of depression, refusal of food, and a most singular and marked physical change. He would begin the outbreak a fairly well-nourished boy, and in the course of a few hours would look as though he had passed through a serious illness; his cheeks and eyes sunken, his features drawn, respiration, temperature and pulse below the normal. Equally remarkable is the rapid recovery of lost ground when reaction once sets in.

The female is essentially vicious, and the boy needs only suggestion to become so; the moral sense is lacking in both, and it is only the force of example and environment that prevents either from joining the ranks of juvenile criminals.

It may be wrong to argue that a possible inherent tendency to spasms may produce a crime as a result rather than a fit, or that the relationship is so close that the criminal has a fit at one time, and at another the crime is substituted for the nervous explosion. "Human character," says Wood, "is the result of the established balance between the will and the intellectual attributes and the emotional forces of the individual. When any of the correlated factors are altered, there must be a corresponding change in character."

Close association with epileptics shows with great distinctness the result of this disturbance of correlated factors. The loss of will, the loss of memory, the lack of ability to inhibit the lower intellectual and emotional brain functions, the development of the passions, the growth of a superficial veneer of good behavior over the thoughts and desires of a satyr or bacchanal kept in suppression only by the fear of a superior strength, the brutal selfish, malevolent, surly, irascible, perverse egotism of epileptics is well known, especially in epileptic imbeciles. The Mr. Hyde of human nature is always in the ascendency, and we find these same characteristics in numbers of criminals, particularly in the younger male and females, who throng our courts and fill our station houses.

We have found out that the juvenile insane show a marked criminal tendency; we know that there is a distinct type of imbecile with the same tendency, which we call the moral imbecile, and I fancy, when each state will assume the burden of care and restraint of her epileptic defectives, that intelligent study will show that this terrible disease drives many of its victims to the penitentiaries, even to the gallows, for hideous crimes against the person, murder, arson, et al.

Proper education of the more juvenile delinquents would probably detect signs of what we have termed pyschical epilepsy, and proper treatment eradicate the symptoms or point out the propriety of life restraint.

# COMMUNICATIONS.

## FLAT-FOOT AND ITS TREATMENT; THREE RECENT CASES OF STONE IN THE BLADDER; LITHOLAPAXY.*

THOMAS G. MORTON, M. D., PHILADELPHIA.

Mr. Chas. S., of Richmond, Va., has suffered from various accidental injuries of the right leg and foot, the first was about fifteen years ago, which was a sprain of the knee from a fall in dancing; after which for many years he suffered considerable lameness; subsequently he twisted or sprained the ankle, and on several occasions this was repeated. A year ago he again injured the ankle, a probable sprain, and until July following was hardly able to walk, always requiring some sort of support; at that time he had a steel sole placed in the shoe, from which he had little if any relief; he then began to have spinal pain and a distressing aching in the neck and back of the head; could not go about except with the aid of a cane, suffered from exhaustion, became insomnious, lost appetite and weight.

On examination, early in January, 1894, I found a weak ankle and extreme talipes valgus. In addition there was asymmetry of lower extremities; the right or weak limb was three-quarters of an inch shorter than the other, and calf measurement showed the right half an inch less in circumference.

A lateral support was applied to the limb to support the weak ankle, and in the shoe, a Gefvert steel-spring arch; the short limb was made equal to the left by adding sufficient to the heel of the right shoe.

Mr. S. reports: "I can hardly realize that after so many years of suffering, and in so short a time, I would be able to walk again without pain. I find the steel spring comfortable, and I find no inconvenience in having it in my shoe; my back and head have been relieved, I presume, by the high heel."

REMARKS.—Either in uterine or early child life the patient had a slight one-sided paralysis which, although arrested early, was sufficient to interfere for a time with the growth of the extremity, and this accounts for not only the ankle weakness, but the variation in the length and size of the right as compared with the left limb. Valgus—indeed, all the varied forms of congenital talipes arise in the same way. Spinal and head pain is frequently associated with and caused by a short limb; the constant shocks the spinal cord and brain are subjected to in certain individuals is quite sufficient to bring about in nervous temperaments, perhaps with impairment of general health, just such a condition.

The weak ankle has in this case been marvellously improved. even in a comparatively short time, by the steel arch.

The spring arch, which I exhibit, is fastened in the shoe directly under the tarsal arch; it is made of two elliptical pieces of steel which are three and a half inches long and two inches wide; one plate is flat, the other is arched on its inner side, which is intended to support the tarsal arch; tne plates are joined together at their outer edge by a stout hinge, and the upper or arched plate on its inner side comes in contact with a lump of rubber which, when pressure is made from above, yields and gives the spring to the foot.

CASE I.—Leon F., aged sixty-six years, living in Kansas, a merchant, had never been sick until about twelve years ago, when he first suffered from bladder irritation, and, finally, with the most aggravated and distressing symptoms of stone in the bladder; subsequently he came to Philadelphia.

On examination, the urethra from the prostatic portion of the canal to several inches in advance was found distended by a series of calculi, impacted and joined together, forming, as it were, a long, continuous stone; the various facets, however, permitted more or less movement.

A median section over the most prominent stone exposed the urethra, and the calculi were readily removed; the stones distended the urethra to such an extent that when removed a finger was readily

*Read before the Phila. Acad. of Surg. February 5, 1894.

introduced into the bladder, in which three calculi were discovered and easily taken out without further use of the knife. Recovery and complete restoration of the function of the neck of the bladder followed.

Early in 1893, or about twelve years afterward, Mr. F. had a recurrence of irritation of the bladder, and later with the usual stone symptoms.

In May he came to this city and a calculus about an inch and a half was found, and on June 1st litholapaxy was performed and the bladder completely cleaned. Ten days later he was quite well and went West, and remained so until the latter part of November when, after slight renal pain, the symptoms of stone reappeared. A stone was found and removed by litholapaxy and without using an anæsthetic; weight, fourteen grains.

*January* 12, 1894. Having since the last operation been free of all bladder symptoms, he had two sharp chills and some fever, and almost at once irritation in the bladder followed; the sound detected a small stone, which was easily grasped by a small Luer crusher, and the stone was removed without breaking; weight, five grains.

25th. After another slight attack of pain and very slight irritation a small stone was seized and extracted; weight, three and a half grains; all symptoms have been relieved.

CASE II.—Col. T. H. R., aged fifty-nine years, came under my care November 11, 1893. Family history: grandfather and father had severe bladder trouble and supposed to have had stone. From a description of an attack through which a brother passed, it was supposed he suffered from renal calculus.

Present attack: about two years ago patient passed a stone for first time, since then stones of varying size have been passed; has had two attacks of renal colic.

In July, 1892, he was subjected to lithotripsy and received little if any benefit; his sufferings were in nowise lessened. In August last he was sounded and declared to be free of stone; his symptoms were judged to result from cystitis.

*November* 16. An examination of the bladder revealed a stone of considerable size; urine contained a large amount of albumin, but no casts.

18th. Litholapaxy was performed, the stone crushed and removed by Bigelow's apparatus.

*December* 9. Patient was free from vesical irritation and left for his home.

The calculus weighed 178 grains.

CASE III.—Mr. W. C. R., aged sixty-six years, consulted me at the request of Dr. J. A. Patterson, of Salem, N. J.

*History.* For twelve years suffered from attacks of rheumatism and sciatica, then for a short time had comparative health. Two years ago began to suffer from irritation of the bladder; the symptoms gradually increased in severity. The urine showed a large amount of pus.

*December* 12. Sounding revealed a large, hard stone.

21st. Litholapaxy and removal of fragments by Bigelow's evacuator; the stone weighed six drachms and fifteen grains, and was uric acid. Ten days subsequently the urine was normal, and all irritation having disappeared, he left for his home quite well.

REMARKS.—The ages of the three cases were respectively fifty-nine, sixty-two and sixty-seven years. Anæsthesia was omitted in one of the operations. In dilating the urethra a No. 31 bougie was used. The bladder was cleansed with boric acid solution and eight ounces of the same allowed to remain during the crushing. Prompt recovery followed in each case. In the first case the patient was free of irritation for nearly five months, then sudden irritation announced the descent of a renal stone; an entire absence of symptoms followed until a lapse of six weeks and two weeks' intervals, when small renal calculi entered the bladder and were promptly removed, using the small duck-bill lithotrite. Piperazine was given to each patient, and directions to have the bladder examined at intervals of four months.

---

DR. PAUL GARNIER, of Paris, has made a special study of those slum children that are the offspring of habitual drunkards. He says: "There is a flaw in the very nature of these young wretches that the psychologist sees clearly and notes with apprehension — the absence of affectionate emotions, and where they did not become lunatics they show 'insensibility and pitilessness.'"

# LIGATION OF THE COMMON AND EXTERNAL CAROTID ARTERIES AND THE JUGULAR VEIN.*

W. W. KEEN, M. D., PHILADELPHIA.

Mr. St. John, a Frenchman, about twenty-five years of age; was first seen at the Presbyterian Hospital in Chicago, August 9, 1893, in consultation with Drs. D. W. Graham and N. Senn. Unfortunately, in consequence of change of residents and absence from the city, the history is imperfect.

About three years before I saw him he had been shot, the ball entering just below the tip of the left mastoid. He was unconscious for a brief time, but when he recovered, either the same day or the next morning, he discovered that his right eye was absolutely blind. In addition to this, his right arm was paralyzed, but whether immediately after the accident or at a somewhat later period was not ascertained. When I saw him, the right arm was the subject of contractures, the result of the old monoplegia. The leg and face was not affected. The aneurismal bruit and thrill were very marked, and could be felt down the left side of the head and neck. There was but little external swelling. The man sought relief on account of the noise produced by the aneurism, which made it impossible for him to do any work.

Operation, August 15, 1893, by the kind request of Dr. Graham. The carotid was laid bare by the usual incision over the anterior border of the sterno-cleido-mastoid, the middle of the incision corresponding to the upper border of the thyroid cartilage. Considerable difficulty was found, even at this stage, in consequence of the inflammatory adhesions resulting from the gunshot wound of three years before, and also from the fact that the vessels lay nearly under the middle of the sterno-cleido instead of under its anterior border. My intention had been, first, if the adhesions (the presence of which I had anticipated) would allow me to reach the internal carotid, that I should tie that and the jugular just above the bifurcation of the carotid; but if the adhesions prevented this, I determined to tie the common carotid and the external, the latter being tied so as to prevent the reestablishment of the current by the anastomotic circulation from the other side. Even the ligation of the external carotid above the bifurcation was quite difficult by reason of the adhesions. It was done just at a point were the first branch was given off, and the ligature was made to include both the external carotid and its branch in one loop. The jugular vien was tied at a point half an inch below the level of the ligature around the common carotid, in order that the necessary injury to the tissues should not be at the same level. The veins were very full, giving thus an additional evidence that the diagnosis of arterio-venous aneurism was correct.

Dr. Graham has kindly written me under date of October 2nd, as follows: "The wound healed practically by primary union. One angle was a little slow in closing, but there was no purulent discharge at any time. The morning after the operation ptosis and immobility of the left eye ball were discovered, although he could turn the globe outward somewhat, and slightly upward. The pupil was not affected, but responded to light. There were no mental disturbances or paralysis. In two or three weeks improvement began in the eye, and when he left the hospital three weeks ago he could keep the lid up nearly in a natural position, and could move the eyeball in every direction, promising complete restoration from the paralysis. He was to report to us occasionally, but I have failed to see him since then."

REMARKS.—I regret very much the imperfect history of the case, but the circumstances made it impossible to get any more complete history. For the same reason no examinations of the eye-grounds were made, either before or since the operation. Fortunately, the absence of a post-mortem prevents our ascertaining absolutely the pathology of the case. The ball after traversing the blood vessels entered the skull at its base, and without doubt cut the right optic nerve between the eyeball and the chiasm. The paralysis of the right arm was due, of course, to the involvement of the left motor cortex, or

* Read before the Phila. Academy of Surgery, February 5, 1894.

fibres proceeding from it. Whether the ball in entering the skull was split in two pieces, one of which injured the left cortex in the arm area, and the other the right optic nerve, or whether the paralysis of the arm was due to an embolus from the arterio-venous aneurism, can only be speculated on. None of the ball was ever found. What the final result as to the aneurism will be is not yet ascertained.

## SUGAR AS AN OXYTOCIC.

F. H. PRITCHARD, M. D., WEAVER'S CORNERS, OHIO.

Professor U. Mosso and Luigi Paoletti, at the conclusion of a mémoire on the Influence of Sugar on the Work of the Muscles, which mémoire was read before the Accademia dei Lincei (*Rendiconto R. Accademmia dei Lincei*, Vol. II, 2 Sem., Ser. 5, fas. 8), suggested "that we hope that it will be able to be used with advantage in therapeutics, to revive, for example, the pregnant uterus, tired out by effort, when expulsion of the fœtus is necessary." A distinct allusion is here made to the possible ecbolic action of sugar. In the *Gazzetta Degli Ospitali*, No. 2,1894, Prof. Bossi, of the Obstetrical and Gynecological Clinic of Genoa, Italy, reports the results which, since the publication of Professor Mosso's experiments, he has obtained with sugar as an oxytocic in a large number of cases. As it was known to have an effect upon the voluntary muscles it was thought probable that it would also act on the involuntary. In these experiences he sought to exclude all sources of possible error as to suggestion. As he was in charge of the Obstetric Guard of Genoa, he distributed to each member a number of powders of finely powdered sugar, each containing thirty grams (about an ounce) with directions to give one powder in cases of uterine inertia and, if requisite, to repeat the dose after two hours. As the members of the Guard are only called in by midwives when there is a relative or absolute uterine inertia, and where something is urgent, these results are worthy of notice. He concludes as follows:

1. In ten out of eleven cases a positive ecbolic result was obtained from an ounce of sugar in eight ounces of water. This effect was observed on an average a half hour after its administration.

2. In some cases the one powder was sufficient to induce expulsion of the fetus.

3. If a second powder were given after two hours, the effect was more pronounced.

4. In no cases were tetanic contractions observed, while on the contrary, the contractions were regular and no incarceration of the placenta was noted.

On account of these favorable results he reports them and thinks that he is justified in recommending the use of sugar as an ecbolic in obstetric practice. It is prompt in its action; is not associated with certain disadvantages as ergot and its preparations, it does not cause tetanic action, is not liable to be followed by incarceration of the placenta or the fetal parts as with ergot and, on account of there being no danger of poisoning, the dose may be increased and repeated without danger to either mother or fetus. It is easily found in any family and hence may be had at all times. It short, he states that it possesses all the advantages of an ideal ecbolic without any disadvantages.

The night next after reading this article I was called to see a healthy German woman in the country, who had already given birth to two children, who are now alive and well. It was then half-past three in the morning. The pains had begun at supper time the evening before, and reappeared at slightly regular intervals, but not with much intensity. On external palpation I found the child with the head presenting and on the left side. Internally I found everything to be normal and the head presenting in the left occipital position. The cervix was well dilated, but there was nearly no bag of waters, the head having forced itself down early and allowing none to escape in front into the cervical sac. The pains came on now and then, but they were not of much consequence from their weakness. I waited a half hour, and then I thought of the sugar and the Italian article. Without any faith

in the measure I took a tablespoonful of granulated sugar, dissolved it in a glass of water and gave the woman a swallow. There was a very slight increase in pains after about twenty minutes when I had her take two swallows of the solution. In twenty minutes more, the pains came on with great intensity. They absolutely gave her no rest, rolled on one after another, and in a short time, one half-hour after the last dose the child was shot out between her thighs. I was somewhat alarmed with the rapidity and intensity of the pains for I feared the consequences of a precipitate birth, but fortunately there was no permanent tear nor inversion, etc. The placenta followed in about two minutes, and there was no more hemorrhage than usual in such cases. After about half an hour she complained of griping pains which I treated by a warm compress and whiskey over the abdomen and went home thinking all would quiet down, in the course of a few hours. But it did not. The pain came on every few minutes all that day so as to be distressing, The next morning at one o'clock, I was called by her husband and told that she was having some "queer spells" that went beyond the comprehension of her mother, the attendant. I hastened down to the house and found that she was suffering from a sort of terrific after pains so severe at times as to cause the sweat to stand out on her face, while the uterus would contract as hard as a billiard ball. I took in the situation at once. The sugar had overdone its work, and given rise to tetanic contraction of the uterus. Hot compresses to the abdomen and paregoric internally relieved them somewhat, but it was only after drop doses of the tincture of gelsemium every hour that they calmed down. The day after that they had disappeared entirely, though the day of the morning when I was called they continued, but were not distressing nor severe.

From the literature and my single experience I conclude that sugar is an efficient oxytocic, and one which is devoid of danger in ordinary and carefully measured doses. Though Bossi states that it will not cause tetanic contractions, my one experience leads me to the contrary view. That employed in graduated and measured doses, at regular intervals, of say, two hours, it will give good service. That it does not increase the force of the heart-beat and other disagreeable symptoms, like quinine when used as an oxytocic; nor like ipecac, cause vomiting nor is it cumbersome and bothersome like the hot douche, but is handy, quite certain, and easily obtained everywhere. That large doses will cause tetanic contractions and induce painful after-pains. That gelsemium, in drop doses of the tincture, is antidotal to this over traction.

---

**Pertinent Facts on Vaccine Virus.**

Keep in a glass-stopper jar in an unheated room in winter and in a refrigerator in summer.

Do not carry in an inside pocket.

Do not use too much water.

Do not abraid too large a surface.

Do not use any dressing.

Do not report until the 8th, or better, the 10th day.

Our plan of operating is as follows:

We scarify by scraping off the scarf-skin from a surface about one-fourth of an inch square over the insertion of the deltoid muscle, scratching the surface thus abraided in two directions.

We touch one side of the ivory point with a drop of water, immediately shaking the excess off; rub this side briskly on the abrasion and then form a paste by using the dry side of the point.

We finish the operation by gently scratching the virus in with the point we have used.

We are then certain of getting some of the vaccine corpuscles within reach of the mouths of the absorbents.

Too much water, with the serum that exudes from the arm, frequently washes away the corpuscles, while too thick a paste, if not pricked in, will dry as a varnish, beyond the reach of the absorbents which have been closed by the rubbing process.

If you protect with a shield, see that it is properly ventilated.

Failures result from

Using unhealthy or poorly fed cattle.

Pressure used in removing Lymph.

The clamor of physicians for colorless points.

Hot mail-cars, drug stores and physicians' offices.

Improper methods of operating.

Old goods, or mucilage and croton-oil points! sold at cut-rate prices, while human lives are sacrificed.

DR. H. M. ALEXANDER.

# TRANSLATIONS.*

## PHYSICAL DIAGNOSIS OF BILIARY CALCULI.

C. Gerhart calls attention to the early symptoms of biliary colic. The attack begins often four to five hours after a hearty meal, or when the food passes into the duodenum, causing, by a reflex action, an expulsion of bile from the gall bladder. This will produce a temporary sensible enlargement of the sac (supposing that obstruction of the duct exists, and the gall cyst retains its distensibility). This enlargement subsides as soon as the stone has passed; the localized inflammation having produced some peritonitis, a circumscribed area of crepitant rales can be heard with the aid of the stethoscope. This, together with pain, may exist some little time after the stone has found its way into the intestine. This latter condition is often greatly ameliorated by applications of ice water. An extension of the peritoneal inflammation to the pleura is but rarely observed. As a most frequent complication, we have an appendicitis due to a mechanical or chronic obstruction. If the attack is prolonged, the liver becomes enlarged and its edges can be easily palpated and often seen, if the patient is emaciated. Transient enlargement of the liver, one of the important symptoms, is also met with in cholelithiasis, or when the ductus communis is obstructed by ascaris lumbricoides, or other catarrhal inflammatory exudations. The head of the pancreas is also the seat of a new growth or swelling, thus producing mechanical pressure upon the duct; on the other hand it is absent in cardalgia or purely nervous hepatic colics.

Cholelithiasis can be excluded if there be an absence of crepitation over the seat of the gall cyst— if there is no enlargement of same, and if after several attacks there have been no calculi found in the fæces.—*Deut. Med. Wochen.*, No. 46, 1893.

—W.

## SACROMA AT THE BASE OF THE SKULL; SECONDARY AFFECTION OF THE TEMPORAL BONE.

Dr. Schwiedof (*Arch. f. Ohrenheilk*, xxxv pg. 39), reports a case of a young man, aet 30, who had suffered for some time of tinnitus aurium, deafness, occasional discharge of pus from both ears. Other symptoms were present which did not belong to mastoiditis; stiffness and pain in the cervical region, headache, dizziness, difficulty in deglutition. The use of Glisson's extension apparatus was of little or no benefit. A diagnosis of tubercular ostitis of the atlanto-occipital joint was made, and it was decided to chisel off the antrum mastoid, with the result of finding a glandular swelling about the size of a pigeon's egg, behind the sterno-cleido-mastoid muscles. There was an absence of empyema or pus beneath the periosteum.

The patient's strength decreased rapidly, other muscles became paralyzed, viz. glosso-pharyngeal, the hypo-glossus, and lastly the vagus became affected (decrease of pulse rate and respiration); this ended in death.

An autopsy revealed a tumor situated at the base of the skull, occupying a space $\frac{2}{3}$ toward the right and $\frac{1}{3}$ to the left of the median line. A careful examination of the petrous portion of the temporal bone could not be made. A histological examination of the tumor proved it to belong to the spindle-celled sarcoma. The early symptoms regarding the disturbances in hearing, are attributed by the author to the early mechanical occulsion of the Eustachian tube. This then becomes an all important symptom in the diagnosis of these diseases; in which opinion he is supported by Gerhardt and Moos. —W.

* Translated for THE MEDICAL AND SURGICAL REPORTER by the translators W. A. N. Dorland, M. D., M. B. Werner, M. D.

## THERAPEUTIC SUGGESTIONS FROM FOREIGN JOURNALS.*

### CREASOTE AND SULFONAL IN WHOOPING COUGH.

In the *Rivista Clinica e Terapeutica*, No. 12, 1893, the following formula is recommended in whooping cough:

℞ Creasote.....25 cgms (grs. iv)
Sulfonal..... 20 cgms (grs. iij)
Syr. tolu.....150 gms (℥v)

Teaspoonful every two hours.

### BORATED SALVES AS DRESSINGS.

Dr. Koehler (*Union Médicale*, No. 39, 1893), employs the following salves as surgical dressings:

℞ Boric acid.....10 gms (℥ijss)
Glycerine.....30 gms (℥j)

℞ Lanoline.....40 gms (℥jss)
Vaseline.....20 gms (℥v)

℞ Lanoline.....50 gms (℥jss)
Vaseline.....10 gms (℥ijss)

### ALKALINE NITRATES IN MALARIAL POISONING.

Dr. Buro (*Gazette des Hôpitaux*, No. 125, 1893) has employed the nitrates of soda and potash in malaria and claims that they are specifics having an action similar to that of quinine. In adults the dose is from one to one and a half grams (fifteen to twenty-two grains) per diem. They may be given either during the intervals or just before the attacks. When it is necessary to prolong their use and increase the dose the preference should be given to the soda salt as it is less toxic and has no effect upon the heart. The taste of these preparations is not disagreeable and they are well tolerated by the stomach.

### EXCORIATIONS IN CHILDREN.

In *L'Union Médicale*, No. 37, 1893, the following ointment is spoken highly of in the excoriations of children:

℞ Salicylic acid.....5 dgms (grs. viij)
Subnitrate of Bismuth.....8 gms (℥ij)
Starch.....6 gms (℥jss)
Rose ointment.....30 gms (℥j)

For external use.

### SULPHATE OF SPARTEINE.

Dr. Rhode (*Gazette des Hôpitaux*, No. 125, 1893), presents the following rules for the employment of the sulphate of sparteine both as a heart tonic and as a diuretic. A dose of five cgms. per diem has always been sufficient in his experience to produce diuresis. In some cases it has been of advantage to associate it with digitalis, convallaria or strophanthus. Association of these diuretics, given in small doses, will yield one results, in rebellious cases, which would not be obtained by single massive doses of any one alone. It also permits one to continue treatment for several weeks. By giving one cgm. of sparteine four to five times a day, the effects begin to be felt after twenty-four hours. As with digitalis an increase of arterial pressure precedes the diuresis. Sometimes a diminution of the pulse rate has been observed where it was accelerated from some pathological cause, but the slowing as remarked after digitalis, has not been observed. It may also be employed in subcutaneous injections, for injections of a 2:100 solution cause neither pain nor inflammation. Its effect upon the pulse is apparent after a few minutes. The quantity of albumen may also diminish after its use, even to complete disappearance. This diminution is real and not apparent from dilution of the urine.

### A DIURETIC IN CARDIAC AND RENAL DROPSY.

In *La Riforma Medica*, 1893, IV, No. 25, as a diuretic in cardiac and renal dropsy, the following formula is warmly recommended:

℞ Fl. Extr. jalap
Fl. Extr. squills.....ää 15 gms. (℥iv).
" jaborandi..... 30 " (℥j).
" digitalis,.....gtts. xxx
Nitrate of potash..... 20 " (℥v).
Angelica wine..... 60 " (℥ij).

A tablespoonful every three hours.

### CHRONIC RHEUMATIC THROAT DISEASES.

Dr. A. Hecht (*Wiener Medizinische Presse*, No. 1, 1894), directs attention to the existence of chronic rheumatic throat diseases and records such a case. A woman of twenty-five years, had suffered or two and a half months, from difficultyf n swallowing, which however, was noti constant. In the morning she could eat her breakfast without pain but when she worked the whole day in the field or was exposed to cold weather pain increased

*In charge of the translator, F. H. Pritchard, A. M., M. D.

considerably. The pain was not always of the same intensity and changed about, now being on the right and then on the left side. Examination of the throat and larynx revealed nothing and hysteria could be excluded. She also complained of pain in the muscles of the back of the neck, and the lateral surfaces of the thyroid cartilage were also sensitive to pressure. As the pain was complained of in the one or the other side the corresponding portion of the faucial arch was painful and reddened. Salicylic acid yielded no results. The disease was first described by Fletcher Ingals, and its characteristic feature is pain in the small muscles and the connective tissue between them and the cartilage, radiating from here to the clavicles. In most cases the pain does not extend over these bounds, but is limited to special parts, principally the posterior arch of the palate, the hyoid bone, especially its large cornua and lateral surfaces. The pain was intermittent and quite severe during changes of weather. On pressure painful points could be made out, degultition was most always, and speaking sometimes, painful. The back and sides of the neck were also occasionally affected. Locally there was more or less redness. Treatment of this obstinate disease is to be directed to the diathesis. Internally salol and the salicylate of soda are to be employed, while locally the following formula is of service:

℞ Muriate of morphine.....25 cgms. (grs. iv).
Carbolic acid
Tannic Acid.....āā 2 gms (gtts. xxx.).
Glycerine,
Distilled water.....āā 15 " (℥iv).

To be applied locally every two or three days.

He effected a cure, in his case, by these means.

---

### PITYRIASIS OF THE EARS AND ITS TREATMENT.

Dr. Albespy (*La Semaine Medicale*, No. 66, 1893), calls attention to this rare disease. It is a desquamating dermatitis of the external auricle and the outer auditory meatus. There is slight desquamation; it is rough to touch, as though the ear had been frozen. Cerumen is no longer formed. The whitish or grayish scales are thicker at the centre than at the periphery and may accumulate in the meatus in the form of a plug. Subjectively the patients complain of itching, roaring in the ears, difficult hearing, a sensation of warmth in the ear, and sometimes of facial neuralgia, from irritation of the endings of the trigeminus in the external ear. It might be confused with the affection described by Wreden as keratitis obturans or seborrhoeic eczema. In the former the disease affects chiefly the deeper portions of the external ear, and with the latter there are vesicles secreting moisture. In pityriasis, the scales on the inner surface present the characteristic streak and it is not observed before the twentieth year. It is due to extension of the disease from the hairy scalp. The hairs in the meatus should be either extracted or cut off and the scales removed by a luke-warm boric acid solution. A pledget of cotton, dipped into a five per cent. solution of nitrate of silver, is then introduced into the ear and left there for twenty-four hours. After this is removed the underlying skin is found to be red but not bleeding. This tamponade is continued until desquamtion no longer takes place, and the walls have become smooth. This once attained, tampons dipped in the following are employed:

℞ Salicylic acid.....3 gms. (grs. xlv).
Canada balsam.....1 " (gtts. xv).
Collodion.....16 " (℥iv).

Under the influence of these tampons, renewed every four to five days, the redness disappears and the epidermis gradually regenerates. Treatment is finished by insufflations of air. Internally one may administer preparations of arsenic.

---

### TREATMENT OF CONDYLOMATA.

Dr. Gemy (*Riforma Medica*, No. 22, iv., 1893) recommends where the removal of acuminate condylomata is impossible, the local application of an astringent powder consisting of equal parts of salicylic acid and powdered sabina. Before its application the affected parts should first be energetically bathed with warm water, to which about six per cent. of Van Swieten's solution has been added. After the local bath, dry them carefully with sublimated cotton before application of the astringent powder. He regards the acuminate condylomata as the product of a coccidium.

---

### PEROXIDE OF HYDROGEN IN STOMATITIS.

Dr. Boennecken (*Wiener Medizinische Presse*, No. 4, 1894) recommends the

peroxide of hydrogen very warmly in the treatment of stomatitis. It will immediately prevent, in a moderately low per cent. solution, development of micro-organisms and has the advantage of not irritating the mucous membranes. A two to three per cent. solution generally suffices, for even if greatly diluted, it possesses strong antiseptic qualities; even a 1:20000 solution, hindering the development of the micro-organisms of putrefaction. If one have a patient with stomatitis, irrigate the mouth with a two per cent. solution for a few minutes and the former penetrating odor will have disappeared. After twenty-four hours use the purulent coating on the ulcers of the edges of the gums will have been cast off, and in forty-eight hours they will have begun to cover with a layer of epithelium. In five to six days even severe cases may be caused to heal.

---

### ICHTHYOL IN DISEASES OF THE GENITO-URINARY TRACT.

Dr. Lohnstein (*Allgemeine Med. Central Zeitung*, No. 103, 1893) has employed ichthyol in genito-urinary affections, and comes to the following conclusions:

1. Ichthyol is an excellent remedy in acute urethritis, in a ½ to two per cent. solution in warm injections, and even in cases where the mucous membrane is especially irritable.

2. In subacute anterior urethritis and above all, in superficial circumscribed affections, it renders excellent service if it can be applied locally through the endoscope.

3. In infiltrating forms of chronic urethritis it is inactive, but on the contrary, it will be of value if alternated with mechanical measures of treatment.

4. In prostatitis, in the form of suppositories, in doses of three to five dgms. (five to seven grains) it removes the inflammatory and irritative phenomena.

5. In pyelitis and nephritis it exerts no beneficial action.

---

### DANGERS OF COCAINE SALVES.

In the *Medinicische Neuigkeiten*, (No. 2, 1894) it is stated that a salve or solution of cocaine, even of two per cent., if applied to the breasts of nursing women, will produce erection of the nipple and, what is worse, a suppression of the milk. This suppression is only temporary and disappears after discontinuence of the drug, yet it seems advisable to warn against employing cocaine in the treatment of fissures of the breast in nursing women.

---

### ANTISEPSIS OF FISSURES OF THE NIPPLE.

Dr. Lepage (*La France Médicale*, No. 4, 1894) claims that the prophylactic treatment of fissures of the nipple is almost an illusion, but it is possible in abscesses of the breast. Compresses, wet with a saturated solution of boric acid, are valuable agents in prevention of mammary abscesses, if they be only continuously applied. He recommends the following solution:

℞ Sterilized water.....450 gms (℥xiv)
Glycerine.....500 gms (℥xvij)
Alcohol.....50 gms (℥jss)
Biniodide of mercury....10-20 dgms (grs. jss-iij)

Since this solution has been employed at the Maternity of Baudelocque, in Paris, the morbidity of nursing mothers has greatly decreased and the health of the children also has been in general improved, as the mothers suffer less and nurse better and more frequently.

---

### TREATMENT OF NEURALGIA.

Prof. Dujardin-Beaumetz (*Rivista Clinica Terapeutica*, No. 12, 1893) advises the following treatment of neuralgia:

Administration of antithermic and analgesic remedies. In hemicrania, antipyrine is to be preferred, while in pains from compression, lightning-like pains and dental neuralgia, acetanilid is the best remedy. In pure neuralgia exalgine is preferred by him. In pains of neuropathic origin phenacetine acts best. Antipyrine is prescribed in daily doses of one to four grams (fifteen grains to one drachm.) Acetanilid is administered in a daily dose of twenty-two grains in three powders. Exalgine is best given in the following formula:

℞ Exalgine,.....2. 50 gms. (grs. xxxvij).
Tinct. of Melissa,..... 10 gms. (℥ijss).
Syrup of Orange Peel,.....150 gms. (℥v).
A ℥bupspoonful morning and evening.

Phenacetine is administered in single doses of seven to fifteen grains, of which two to three are taken in twenty-four hours.

# SELECTED.

## MALPRACTICE AS DEFINED BY LAW.*

The following extracts are taken from the official report of the address on "Malpractice with Reference to the Legal and Medical Professions." They present an interesting definition of the relations of the professions of law and medicine, and of the responsibility which both bear to the public:

### IMPLIED OBLIGATIONS OF THE PROFESSIONS.

The obligation of the two professions is the same. Physicians, surgeons, dentists, druggists and lawyers, by holding themselves out to the world as such, impliedly contract that they possess the reasonable and ordinary qualifications of their profession, and are consequently under a duty to exercise reasonable and ordinary care, skill and diligence toward those who employ them. The world has not time to inquire into the proficiency of every professional man; hence, it presumes him to be furnished with that amount of skill which he is under obligation, by virtue of his calling, to possess. It may and does vary widely among men, but it must at least be sufficient to entitle him to a recognized place among his own fraternity. If, therefore, by illegally assuming a title, or assuming one he is incompetent to fill, he holds himself out as a practitioner of any science, when he does not possess the required qualifications, and induces the public to employ him, he is a wrongdoer *ab initio*, and any person injured by his performances has an action against him.

The courts have ruled that no attorney can be held to infallibility of judgment or to a warranty of the result of his efforts. Attorneys do not profess to know all the law or to be incapable of error or mistakes in applying it to the facts of every case, as even the most skillful of the profession. What he is responsible for is ordinary skill, diligence and care, having reference to the nature of the business he undertakes to do, and for any failure to exercise these, an action may be maintained by his client against him.

*Delivered before the Society of Medical Jurisprudence at the Academy of Medicine, November 13, 1893, by Hon. David McAdam, Judge of the New York Superior Court.

### MALPRACTICE DEFINED.

Malpractice is bad or unskillful practice in a physician or other professional person whereby injury is caused. Blackstone says concerning it: "For it hath been solemnly resolved that malpraxis is a great misdemeanor and offence at common law, whether it be for curiosity and experiment or by neglect, because it breaks the trust which the party had placed in his physician, and tends to the patient's destruction" (3 Black. Com., 122).

Malpractice may be divided into three parts—1. Wilful; 2. Negligent; 3. Ignorant.

Wilful takes place when the physician purposely administers medicines or performs an operation which he knows and expects will result in damage or death to the individual under his care.

Negligent malpractice comprehends those cases where there is no criminal or dishonest object, and includes gross negligence of that attention which the situation of the patient requires.

Ignorant malpractice is the administration of treatment calculated to do injury, and which does harm, and that which a scientific medical man would know is not proper.

Malpractice can only be affirmed where the physician has set aside established principles and neglected to employ means which are universally held to be necessary in the given case. If medical men fail to discharge their duty in a skillful and attentive manner, the law will grant redress to the party injured by their neglect or ignorance, in the form of an action on the case, as for a tortious misconduct, and no fees can be recovered.

### TESTS OF RESPONSIBILITY.

From the leading cases the following propositions may be extracted:

1. If the defendant acted honestly and used his best skill to cure, and it does not appear that he thrust himself in the place of a competent person, it makes no difference whether he was at the time a regular physician or surgeon or not.

2. To constitute guilt, gross ignorance or negligence must be proved.

3. A defendant who, with competent knowledge, makes a mistake in a remedy is not answerable; but it is otherwise when a violent remedy, shown to have occasioned death, is administered by a person grossly ignorant, but with average capacity, in which case malice is presumed.

4. Where competent medical aid can be had the application of violent remedies by an ignorant person, though with the best of motives, involves him in criminal responsibility.

5. Express malice, or an intent to commit a personal or social wrong, always makes the practitioner criminally responsible. As physic and salves were in use before physicians and surgeons, the common law provided that if a party employ a person as a surgeon, knowing him not to be one, he had no civil remedy; yet if a person of no medical education, in a case where professional aid might be obtained, undertakes to administer medicine which may have a dangerous effect, and thereby occasions death, such person is guilty of manslaughter.

Many of these matters are now regulated by statutes, which prescribe the rights and liabilities of medical men, and those who assume to practice as such without the necessary credentails. These provisions in the different states are, of course, controlling. In an action against a physician for malpractice the question is not whether he is skilled in his profession, but whether he treated this particular case properly. The question of skill in his profession is material, but not controlling, the main contention being whether he treated the case in hand according to scientific principles.

The physician has no exclusive privilege of absolution from wrong-doing. He derives none from his profession, and becomes responsible, therefore, for any damages to the health or for any disfigurement of the person of a patient, which are directly traceable to his want of skill or diligence.

### WHAT CONSTITUTES SKILL AND DILIGENCE BY MEDICAL MEN.

The reasonable and ordinary care, skill and diligence which the law requires of physicians and surgeons is such as physicians and surgeons, in the same general neighborhood, in the same general line of practice, ordinarily have and exercise in like cases. In a Pennsylvania case a surgeon was sued for alleged malpractice in the setting and treatment of a broken limb. The court charged the jury "that the defendant was bound to bring to his aid the skill necessary for a surgeon to set the leg so as to make it straight and of equal length with the other, when healed; and if he did not he was accountable in damages, just as a stonemason or bricklayer would be in building a wall of poor materials, and the wall fell down; or if they built a chimney and it would smoke by reason of want of skill in its construction. They could not only recover for building, but would be accountable for damages." This ruling was reversed no appeal, and the Appellate Court laid down this rule:—

"The implied contract of a physician and surgeon is not to cure—to restore a limb to its natural perfectness—but to treat the case with diligence and skill. The fracture may be so complicated that no skill vouchsafed to man can restore original straightness and length; or the patient may, by wilful disregard of the surgeon's direction, impair the effect of the best conceived measures. He deals not with insensate matter, like the stonemason or bricklayer, who can choose their materials and adjust them according to mathematical lines; but he has a suffering human being to treat, a nervous system to tranquillize and a will to regulate and control."

The true measures of skill required is that ordinarily exercised in the profession by the members thereof as a body—that is the average of the reasonable skill and diligence ordinarily exercised by the profession as a whole, not that exercised by the thoroughly educated nor well educated.

The medical man must not only possess the required skill, but must exercise it in the case at hand, and in the manner best calculated to bring about beneficial results.

### DIFFERENT SCHOOLS OF MEDICINE.

The law does not favor any particular school of medicine, and the treatment of a physician is to be tested by the principles of that school to which he belongs.

Homeopathy and allopathy now stand on the same footing before the law.

To constitute a school of medicine under this rule, it must have established rules of practice for the guidance of all its members, as respects principles, diagnoses and remedies, which each member is supposed to observe in any given case. If the practitioner proceeds without such a system of fixed principles or formulated rules, he does not belong to "a school of medicine," and he is held to the duty of treating his patient with the ordinary skill and knowledge of physicians in good standing who practice in his vicinity.

SKILL REQUIRED OF EMPIRICS.

One not a regular physician, but holding himself out as capable of treating particular maladies, is bound to exercise the skill and care of the general physician in the treatment of such maladies. This upon the ground that the law makes no allowance for quackery; it demands qualifications in the profsesiôn, and will require empirics to make their professions of skill and ability good, or answer for the consequences. The same rule has been applied to clairvoyants. For unskilfull treatment the attendant is liable.

As Lord Ellenborough said: The farrier who undertakes to cure my horse must have common skill, at least, in his business, and that is implied in his undertaking. * * * A surgeon would be liable for ignorance, and justly responsible for damages, for having adventured upon the exercise of a profession without the ordinary qualifications of skill, to the injury of a patient.

It is sufficient to sustain a verdict that the party held himself out as a physician. Issuing circulars signed with his name having "Dr." prefixed is enough.

LIABILITY OF VOLUNTEERS.

A person who, without special qualifications, volunteers to attend the sick can, at most, be only required to exercise the skill and diligence usually bestowed by persons of like qualifications under like circumstances. Thus (to put a case borrowed from Mohammedan law), "If a person will knowingly employ a common mat maker to weave or embroider a fine carpet he may impute the bad workmanship to his own folly." In other words, a patient is generally entitled to receive that which you lead him to believe he may expect.

EFFECT OF LOCALITY UPON STANDARD OF SKILL.

As the law discriminates between the metropolitan and rural bar, so it distinguishes between the city and country physician, by providing that the locality in which a physician or surgeon practices is to be taken into account. One practicing in a small town or sparsely settled country district is not to be expected to exercise the care and skill of one residing in, and having the opportunities afforded by, a large city. He is bound to exercise the average degree of skill possessed by the profession in such localities generally.

The term "rural practitioner" here used, refers to those who practice in small towns away from the facilities of the "metropolitan practitioner," and not to those in populous places near the cities where the opportunities of the different practitioners are equal. Negligence is the absence of care, according to the circumstances; and the law, exacting as it is in many matters, does not require impossibilities, nor hold people to implied responsibilities, which, in the nature of things, they never intended to assume. The implied obligation in this regard may be said to be that which both parties must have understood, but did not deem necessary to express.

STATUS OF SPECIALISTS.

A professional man who devotes himself to a particular branch of his calling, legal, medical or surgical, and holds himself out as a specialist therein, impliedly undertakes that he possesses superior knowledge and ability in respect thereto as well as its technics, and the degree of skill demanded of him must, in the nature of things, conform to the grandeur of his representations, express or implied.

An oculist may be held liable for failure to exercise as high a degree of skill as other surgeons of that specialty exercise when he holds himself out as possessing such skill.

NO IMPLIED WARRANTY TO CURE.

We have found that the lawyer neither guarantees the success of his proceedings in a suit nor the soundness of his opinions. The same rule applies to the medical man.

There is no implied warranty on his part that he will effect a cure. Failure of a surgeon to accomplish the desired result

does not of itself render him liable for malpractice; the test is whether he has exercised reasonable skill and attention in his treatment. His obligations, like that of the lawyer, is merely to bring to the case in hand the average skill of the profession in the vicinity, with the care commensurate to its importance and the consequences likely to follow.

ERRORS OF JUDGMENT.

Medical men, like lawyers, are not liable for mere errors of judgment, unless it be so gross as to be inconsistent with reasonable care, skill and diligence.

Thus in Fisher *vs.* Nicholls, (2 Ill. App., 484), the appellant asked the court to instruct the jury, "that if they believe the defendants used ordinary skill and care in the treatment of the plaintiff's hand, and made a mistake in judgment, then the defendants are not liable for the result of such mistakes under the law." This instruction the court refused to give as asked, but gave it with the following modification: "Provided the defendants, in making up their judgment, did not disregard the well settled rules and principles of medical science." This request as modified, conforms to the rule already laid down concerning the skill to be bestowed by the medical man to his patient.

The burden of proof is upon the plaintiff in all actions for malpractice to show that there was a want of due care, skill and diligence, and that the injury was the direct result of such want of care, skill and diligence.

The mere failure to affect a cure raises no presumption of a want of care or skill.

A physician and surgeon engages to bring to the treatment of his patient care, skill and knowledge, and while, when exercising these, he is not responsible for mere errors in judgment, he is chargeable with knowledge of the probable consequence of an injury, or of neglect in his treatment or unskillful treatment.

ERRORS IN DIAGNOSIS.

An error in diagnosis is sure to be followed by improper treatment, and is, therefore, of importance.

The courts have held that the right of a physician to be compensated for his services depends upon the diligent exercise under his employment of the skill which commonly pertains to his profession; that the rule applies as well to the ascertainment of the patient's disease as to its treatment, and the fact that the physician erred as to the disease and treated the patient for one he did not have, will not defeat the physician of compensation.

A surgeon possessed of the requisite knowledge is not responsible for errors of judgment or mistakes in a case in which there are reasonable grounds of doubt and difference of opinion, but is chargeable only with error arising from want or failure to exercise reasonable skill and diligence.

In Gedney vs. Ringsley (41 St. R.; 794 s. c., 16 Supplt, 792), it appeared that the plaintiff injured her arm, and defendant (a surgeon) examined it, but discovered nothing more serious than a bad bruise. In fact, the arm was fractured, and by reason of the delay in discovering the fracture the injury became irreparable. In an action for damages the defendant's evidence tended to show that the arm was so swollen that a complete examination could not be made, and that plaintiff told him not to call again until she sent for him. Held, that if this were found to be true, no recovery could be had.

CONSENT TO SURGICAL OPERATIONS.

If physicians attending a woman deem it necessary, for the preservation and prolongation of her life, to perform an operation, they are justified in doing so if she consents, whether her husband consents or not. As a rule, anything warranted by good practice and not objected to by the patient is authorized. This is evidenced by the numerous operations constantly performed in efforts to save or prolong life, some of which result disastrously, and yet no one would impute either malpractice or manslaughter. These are more than offset by the numerous, and sometimes marvellous, results of a beneficial character brought about by similar operations upon others.

GRATUITOUS SERVICES.

The mere fact that a physician or surgeon renders services gratuitously does not affect his duty to exercise reasonable and ordinary care, skill and diligence.

Treating a patient gratuitously gives no license to experiment on him or to do any negligent act toward him. He puts him-

self in professional hands, and has the right to expect medical treatment according to the ability of the physician or surgeon in charge. "It is the duty of every artificer to exercise his art rightly and truly as he ought." This is peculiarly the duty of professional practitioners, to whom the highest interests of man are often necessarily intrusted. The law has no allowance for quackery. It demands qualification in the profession practiced, not extraordinary skill, such as belongs only to a few men of rare genius and endowments, but that degree which ordinarily characterizes the profession.

A physician employed by a city to treat patients in an almshouse will not be relieved from liability to a patient therein for failure to exercise ordinary care and skill, although he is paid by the city and not by the patient.

CONSULTATION WITH OTHERS.

If a physician or surgeon is not competent, or feels that he is not competent, to treat a case properly, it is his duty to recommend the employment of another, but if he is competent and so considers himself, and is in doubt concerning the case, he should use his best judgment as to consultation with other physicians or surgeons. He cannot bring in consulting physicians or surgeons without the consent of the patient, so as to obligate him to pay their fees, unless, perhaps in a very extreme case, where dire necessity furnishes the authority.

ADOPTION OF LATEST METHODS AND APPLIANCES.

Physicians and surgeons should keep up with the latest advance in medical science, and use the latest and most improved methods and appliances, having regard to the general practice of the profession in the locality where they practice, and it is a question for the jury to decide from all the circumstances of the case whether the physician or surgeon has fulfilled his duty in that respect.

If they depart from generally approved methods of practice, and the patient suffers an injury thereby, the medical practitioner will be held liable, no matter how honest his intentions or expectations were of benefit to the patient.

The failure to use the most improved methods is not conclusive evidence of negligence, if those used were reasonably safe, and such as were employed by other reputable practitioners in the neighborhood, no liability is incurred. Yet it is advisable for all to recognize the progress of science and keep abreast of it to avoid charges which are easily made and are lasting in their effects, though unwarrantable by the facts.

PARTNERSHIP LIABILITY.

All the partners are liable for malpractice by any member of the firm. The ground of liability is, the contractual relation, for the gist of the action is its breach either by malfeasance or misfeasance.

It will not do for an eminent practitioner to associate himself in business with a "quack," and after holding him out as a competent practitioner, impose upon the public and then be allowed to avoid the responsibility. Many people might be induced to receive treatment from the partner of a well-known practitioner, who would never have thought of employing him, but for the partnership relation and the holding out of the individual as one worthy of such association. While malpractice is a tortious act, the true source of liability is the contractual relations, which is with the firm, and it must answer for its breach. In other words, it must take the burdens with the benefits.

This doctrine of privity of contract does not confine the remedy to the employer; for if a surgeon treat a child unskillfully, he will be liable to the child, even though the parent contracted with the surgeon.

CONTRIBUTORY NEGLIGENCE OF PATIENT.

If the patient in any way contributes to the injury by his fault or neglect, he cannot recover for malpractice by the physician or surgeon.

If the patient by refusing to adopt the remedies or comply with the directions of physicians, frustrates, or defeats the endeavors of the physician, or if he aggravates the case by his misconduct, he cannot charge to the physician the consequences due directly to himself.

When a liability for malpractice is established, proof that the patient, after the liability was incurred, disobeyed the orders of the physician, and so aggravated the injury, does not discharge the liability; it simply goes in mitigation for damages.

DOCTORS MUST KEEP SOBER.

There is no law except that of propriety, which requires a lawyer to remain sober; but an express statute enjoins this upon the medical fraternity in these words: "A physician or surgeon, or persons practicing as such, who, being in a state of intoxication, administers any poison, drug or medicine, or does any other act, as a physician or surgeon, to another person by which the life of the latter is endangered or his health seriously affected, is guilty of a misdemeanor." Another section provides: "A physician or surgoon, or persons practicing as such, who being in a state of intoxication, without a design to effect death, administers a poisonous drug or medicine, or does any other act, as a physician or surgeon, to another person which produces the death of the latter is guilty of manslaughter in the second degree." Medical men who decline to drink on account of these admonitions may be looked upon, therefore, as models of "statuary sobriety."

DOCTORS SHOULD BE LAWYERS, AND VICE VERSA.

Blackstone, in his "Commentaries," says: "The science of medical jurisprudence has of late years attained to special prominence and importance; inasmuch, also, as the evidence of skilled witnesses is justly deemed entitled of much weight, some general acquaintance with legal principles and the nature of criminal offenses is suggested for those professing the faculty of physic as desirable and useful." Apropos to this let us add the suggestion that inasmuch as there are many cases of contested wills in which the testamentary capacity of the testator is called in question, and many cases of especial prominence and importance wherein the mental condition of the principal party is directly in issue, some general acquaintance with the medical science, and the nature, cause and effects of such things, is suggested for those professing the profession of the law as not only desirable and useful, but necessary to the proper presentation and protection of the rights of their client, and the proper cross examination of the medical experts. The one would seem to follow the other as the night the day.

QUACKS AND SHYSTERS.

To call a person lawfully practicing as a physician a "quack" is in effect charging him with a want of the necessary knowledge and training to practice the system of medicine he undertakes to bestow. In other words, a "quack" is an ignorant pretender to knowledge he does not possess. The term "shyster" has practically the same meaning in the legal profession. Thus, in Wakley vs. Healy, 7 C. B., 591, it was held that publishing in writing of a barrister, that he was "a quack lawyer and imposter" is actionable.

The word "shyster"—defined by Webster to mean a trickish knave, one who carries on any business, especially a legal business, in a dishonest way—is evidently capable of having reference to the professional character and standing of a lawyer.

In an action of libel it was said that the designation "pettifogging shyster" must mean an unscrupulous practitioner who disgraces his profession by doing mean work, and resorts to sharp practice to do it.

It would be a good thing for the public, as well as for the two learned professions, if the ignorant pretenders referred to were obliged to designate themselves "quack doctors" and "shyster lawyers" upon their signs and cards. The government, during the war, stamped upon every bogus greenback it came across the word "counterfeit." These cabalistic marks prevented imposition.

The suggestion made, if carried out, would save the good name of the legal and medical professions from much of the abuse they now receive.

LEGAL POSITION OF DENTISTS.

The teeth and the gums of the mouth are important parts of the human body. The pulling of teeth is an art or profession akin to surgery. Indeed those engaged in it are known as "surgeon dentists," and the same degree of skill is exacted of them as of the other professional men, and, substantially, the same rules govern their operations.

In Keily vs. Colton, the defendant, who was a dentist, undertook to extract a tooth while the patient was under the influence of an anæsthetic called "laughing gas." In extracting the tooth the forceps slipped and part of the tooth went down the plaintiff's throat, causing coughing and

vomiting, which continued at intervals for about four weeks, at the end of which time, during one of these attacks of coughing, the tooth was thrown up and relief followed. Held, that while the patient was under the influence of an anæsthetic, which deprived him of the use of his faculties, the defendant was required to use the highest professional skill and diligence to avoid probable dangers, and that the circumstances presented were sufficient to warrant the finding by the jury of negligence.

LIABILITY OF DRUGGISTS.

The rule of libility of a druggist who delivers a deleterious drug to one who calls for a harmless one is the same as that which governs the liability of professional persons whose work requires special knowledge and skill, and a person is not legally responsible for any unintentional consequential injury resulting from a lawful act when the failure to exercise due and proper care cannot be imputed to him.

An action against a druggist for an error of his clerk in compounding a prescription rests upon negligence, and a right of recovery does not arise from the mere fact that a drug given was not included in such a prescription, as the defendent is entitled to have the question of the competency of his clerk and the exercise of due and proper care on his part submitted to the jury.

In such case, when the defendant assumes to fill the prescription, undertakes that he possesses the ordinary skill of a druggist or apothecary, and that he will exercise due and proper care in putting up the medicine required, the degree of care being proportionate to the gravity of the injury that would necessarily result from a want of care, the failure to exercise due and proper care is the only ground upon which a recovery can be had in such action.

One who is ignorant of the properties of a poisonous drug is liable to a criminal prosecution for a negligent sale or use thereof.

A druggist who grinds medicines in a mortar which has been used to grind poisons without properly cleansing it, is liable to one injured by means of such careless use. So of a druggist on shipboard who neglects cleansing drinking utensils after using them with poisonous substances. So of a druggist who sells morphine instead of quinine, which causes death.

A druggist who sells a deadly poison as a harmless medicine is liable, and one who labels a deadly poison as a harmless drug is liable for all consequences.

LIABILITY OF CORPORATE INSTITUTIONS.

While the attending physician may be liable for malpractice it does not follow that counties are in reference to poorhouses, nor hospital corporations or proprietors in reference to their institutions. Thus, in Harris vs. Woman's Hospital (27 Abb. N. C., 37; s. c., 39, St. R., 98; 14 Suppt., 881), it was held that a public charitable hospital is not liable for injuries sustained by an inmate from the actual negligence of a medical attendant, if it is shown that the institution exercised due care in the selection.

REQUIREMENTS OF EVIDENCE.

Whether a physician has in a given case adopted the proper treatement is a question on which the opinions of medical men of the same school may be received in evidence, and they may state whether, in their opinion, the treatment was proper or not. In other words, whether it was in conformity to the practice of the profession.

A defendant may state what, from his study and experience, he deems proper treatment of the case in question, but not what success he had in other cases. The chief reliance in malpractice cases must be medical testimony, which, in the nature of things, comes from other members of the profession, and is of the character known as the testimony of experts, and consists of opinions founded on facts, observations and the like.

An expert cannot be required to pass upon or draw inferences from the evidence given by another witness.

An expert may be qualified by study without practice, or by practice without study. But mere observation without either is insufficient. Expert evidence, though useful as a guide, depends upon its value as found by the Court or jury, and is never conclusive, as the Court or jury may apply their own experience and good judgement to the subject.—*R. I. Med. Sci. Mo.*

# THE MEDICAL AND SURGICAL REPORTER

ISSUED EVERY SATURDAY

Address care P. O. Box 843, Philadelphia, Pa.

HAROLD H. KYNETT, A. M., M. D.
Editor

RODERIC C. PENFIELD
Publisher

147-149-151 North Tenth Street, Philadelphia

**TERMS:**—Three Dollars a year, strictly in advance. Sent four months on trial for $1.00.

**REMITTANCES** should be made payable only to the Publisher, and should be made by Postal Note, Money Order or Registered Letter.

**NOTICE TO CONTRIBUTORS:**—We are always glad to receive articles of value to the profession, and when used they will be paid for, or reprints supplied, as the author may elect. Where reprints are desired, writers are requested to make a note of that fact on the first page of the MS. It is well for contributors to enclose stamps for postage, that the articles may be returned if not found available.

SATURDAY, MARCH 17, 1894.

## EDITORIAL.

### INTERNATIONAL SANITARY CONFERENCE.

The Sanitary Conference is a remarkable demonstration of the importance in public affairs achieved by modern medical science. The Conference, now being held in Paris, is not a gathering of reformers to propagate a pet theory, but is a meeting of medical experts, who are the official representatives of a number of governments. It is not the first assemblage of sanitary experts seeking the same end, as similar conferences had previously been held at Constantinople, Rome, Venice, and more recently at Dresden; but the present conference is peculiar in the latitude of its powers and in the authority conferred upon it by the participating governments. The object sought by such conferences has been measures for preventing the spread of infectious and contagious diseases, especially those of an epidemic form; and the object of the present meeting is to formulate and recommend measures which can be universally enforced to prevent the spread of such diseases, with special present reference to cholera.

At the Dresden conference it was decided that whenever cholera broke out in any country, other nationalities should be notified of the fact at once. This rule, however, has not been observed, as is evidenced by the strenuous efforts of the French authorities to conceal the prevalence of cholera at Marseilles last year. In February, 1893, there were 102 deaths from cholera at Marseilles and foreign governments were not duly warned. Again the epidemic broke out in May and lasted during the summer months causing 767 deaths, and yet nothing was done. That the United States was spared an invasion of cholera from this source, must be attributed to the very efficient enforcement of the provisions of the new national quarantine law, so ably carried out under the direction of Surgeon-General Wyman, U. S. M. H. S.

The Paris conference is composed of the representatives of seventeen different nations, including the United States, the principal European powers, British India, Persia and Turkey.

Experience has shown the futility of attempting to prevent the spread of cholera and at the same time permit the sources of the epidemic to remain in full activity.

Much may be done by the enforcement of quarantine measures to mitigate the ravages of the epidemic, but to stamp out the disease requires the elimination of its starting point. The necessity of going to the root of the evil involves many questions not only of science, but diplomacy, and is especially difficult from the fact that it concerns the religious convictions of an immense proportion of the population of the Eastern world.

It is agreed that the principal centre from which cholera spreads in all directions, is Mecca, the Holy city of the Mohammedan. That Mecca is the objective point of pilgrimages from all portions of the Eastern world, accounts for the concentration of cholera in that city, brought there by pilgrims and carried from thence by returning pilgrims. A pilgrimage of Mecca is the religious ambition of every follower of the Prophet. To have accomplished such a pilgrimage assures the Mohammedan of religious distinction. To die in the effort to become Hadji, insures entrance to Paradise, and as the Mohammedan is a fatalist, neither death, nor hell, nor any other creature can dissuade him undertaking the trip to the Holy city.

To succeed in regulating these pilgrimages and enforcing the simple precautions necessary to prevent cholera reaching Mecca and spreading from thence over the entire world, without precipitating a terrible religious war, requires the active and constant cooperation of the Turkish and Persian governments. It will not be an easy matter to enlighten these governments and arouse them to continuous and intelligent action.

The success of the British government in anticipating and preventing the inevitable epidemic of cholera following the great Indian Fair at Hardwar, by the strictest enforcement of inspection, isolation and other sanitary measures, shows that the epidemic may be prevented, even at the start; and that too, without seriously interfering with the coming and going of the population. The suppression of cholera at Hardwar, will be of considerable aid in handling the situation at Mecca, not only by force of example but because the fair at Hardwar brought together people from all parts of India, the home of cholera, thus furnished a most effective centre for its propagation throughout the world and, because of the large number of Mohammedan residents of India, became the direct source of supply of cholera to Mecca.

Mr. Earnest Hart, in his articles on cholera, has given a most vivid presentation of the filthy and unsanitary conditions existing at Mecca, and of the inconceivably disgusting practices of the pilgrims in their efforts to secure holiness. And he has likewise shown that the difficulties of securing the proper sanitary conditions are spiritual rather than material, as the physical aspects of the locality present no mechanical obstacles.

In 1881, a quarantine station was opened on the island of Camaran, at the entrance of the Red Sea. Curiously enough, cholera has been more prevalent since the opening of that station than it was before. For instance, there were epidemics in 1865, '66, '72 and '76, before the establishment of this station. Since then, cholera has been epidemic in 1881, '82, '83, '90, '91 and '93; or, during the twelve years preceding the establishment of this quarantine station for the pilgrims there were four epidemics of cholera at Mecca, and during the twelve years following its establishment, there have been six cholera epidemics. This fact, however, does not operate against the importance of establishing sanitary precautions, but it does most thoroughly demonstrate the criminal folly of making an image of science and worshiping it under the belief that it is a potent spirit.

It is to be hoped that the Paris conference will succeed in devising measures that will accomplish the desired end.

# ABSTRACTS.

## LEGAL REQUIREMENTS FOR THE PRACTICE OF MEDICINE IN THE UNITED STATES.

So many changes have been made in the legislation regulating the practice of medicine in this country during the past three years, that the Illinois State Board of Health will include, in its forthcoming Report on Medical Education, the text of all laws on this subject in force at the beginning of the present year in the several States and Territories of the United States, and in the provinces of the Dominion of Canada. From this forthcoming Report, through the courtesy of the Secretary of the Board, Dr. J. W. Scott, some data have been gathered which will be of interest to the spring crop of new graduates, and to medical men generally.

Of the six New England States, Maine, Massachusetts, New Hampshire and Rhode Island have no legal requirements for the practice of medicine. Connecticut has adopted a medical practice act which went into effect Oct. 1, 1863, and in Vermont the law requires the registry of a diploma indorsed by a Board of Medical Censors or of a certificate of satisfactory examination by one of these Boards.

Exclusive of the four States first named, the other States and Territories may be roughly grouped into the following three classes:

In Alabama, Arkansas, Florida, Maryland, Minnesota, Mississippi, New Jersey, New York (act of May 9, 1893), North Carolina, North Dakota, Pennsylvania (after March 1, 1894), South Dakota, Texas, Utah, Virginia and Washington, the diploma confers no right to practice and has no legal value, except, in some cases, to give its professor standing before an examining board. The right to practice in each of these sixteen States is determined by individual examination before boards of examiners created by law.

In California, Colorado, Connecticut (since October, 1893), Delaware, Illinois, Iowa, Kentucky, Louisiana, Missouri, Montana, Nebraska, New Mexico, Oklahoma, Oregon, Tennessee, Vermont and West Virgina, the diploma is subject to supervision of some designated body vested by law with authority to determine its validity as evidence of its possessor's qualifications for the practice of medicine. Failing the possession of such a recognized diploma, the right to practice may be acquired by passing a satisfactory examination.

In Arizona, Georgia, Idaho, Indiana, Kansas, Michigan, Nevada, Ohio, South Carolina (since the repeal of the Act of 1888), Wisconsin and Wyoming, the presentation of any kind of a diploma—provided only that it be from a "chartered" medical institution—is the sufficient warrant in law for country clerks, clerks of courts, registrars of deeds and similarly qualified judges of medical fitness to admit to practice.

Following is a résumé of the legal requirements for practice in each State and Territory of the United States, in force Jan. 1, 1894:

Alabama.—A certificate of successful examination by the State (or a county) Board of Medical Examiners. Diplomas confer no right to practice.

Arizona.—Registry, with a county recorder, of an unrevoked, uncancelled "diploma regularly issued by a medical college properly and lawfully organized under the laws of the State wherein said college shall be located."

Arkansas.—A certificate of successful examination by the State (or a county) Board of Medical Examiners. Diplomas confer no right to practice.

California.—A certificate issued on the diploma of a college in good standing or upon a successful examination by one of the State Boards of Medical Examiners—regular, homeopathic or eclectic.

Colorado.—Similar to California, except that there is but one State Board of Medical Examiners.

Connecticut.—A certificate of registration of the diploma of a college "recognized as reputable by one of the chartered medical societies of the State," regular, homeopathic, eclectic; or a certificate of satisfactory examination by a committee appointed for the purpose by the State Board Health.

Delaware.—A certificate based upon the registration of a diploma from "a respectable medical college," or upon "a full and impartial examination by the State Board of Medical Examiners."

District of Columbia.—Nominally the indorsement of a diploma, or an examination, by a committee of the District Medical Society; practically no requirement.

Florida.—A certificate of satisfactory examination by the State (or a district) Board of Medical Examiners. Diplomas confer no right to practice.

Georgia.—The registration of a diploma from any "incorporated medical college, medical school or university." The clerks of the Superior Courts are the sole judges of the diploma as evidence of fitness for medical practice.

Idaho.—The record of a diploma at a county seat.

Illinois.—A certificate issued by the State Board of Health upon the diploma of a legally chartered medical institution in good standing as determined by the Board, or upon a satisfactory examination by the Board.

Indiana.—The registration, in a county clerk's office, of a diploma "from some reputable medical college."

Indian Territory.—*a.* Cherokee Nation: An examination by the Board of Medical Examiners; *d.* Choctaw Mation: A certificate by the Board of Medical Examines; *c.* Creek Nation: Payment of $25 annually as a license fee.

Iowa.—Similar to Illinois.

Kansas. — The registry of a diploma from "some respectable school of medicine," or of a certificate of qualification from some State or county medical society.

Kentucky.—A certificate from the State Board of Health issued upon the "diploma of a reputable and legally chartered medical college."

Louisiana.—The record of a diploma from "any medical institution of credit and respectability" after indorsement by the State Board of Health.

Maine. — No legal requirement. In 1887 an act to regulate the practice of medicine was passed by the Legislature but was vetoed by the Governor.

Maryland.—A certificate issued upon a satisfactory examination by the State Board of Medical Examiners. Diplomas confer no right to practice.

Massachusetts.—No legal requirement.

Minnesota.—Similar to Maryland.

Mississippi.—Similar to Maryland—except that the examination is made and the certificate issued by the State Board of Health.

Missouri.—Similar to Illinois.

Montana. — Ten years of practice; a certificate upon the diploma of a college "in good standing," or upon an examination by the State Board of Medical Examiners.

Nebraska.—A certificate issued by the State Board of Health upon the diploma of "a legally chartered medical school or college in good standing," as defined in Section 8 of the Act of July, 1891.

Nevada.—The record of a diploma from "some regularly chartered medical school."

New Hampshire. — No legal requirement.

New Jersey.—A license issued upon a successful examination by the State Board of Medical Examiners. Diplomas confer no right to practice.

New Mexico.—A certificate upon the diploma of a legally chartered medical institution in good standing, or an examination by the Territorial Board of Medical Examiners.

New York.—A license issued upon a successful examination by one of the State Boards of Medical Examiners—regular, homeopathic, eclectic. Diplomas confer no right to practice.

North Carolina.—A license issued upon a successful examination by the State Board of Medical Examiners. Diplomas confer no right to practice.

North Dakota.—Similar to North Carolina.

Ohio.—The diploma of a respectable school of medicine, or a certificate of qualification from a State or county medical society.

Oklahoma.—A license issued by the Superintendent of Public Health upon a medical diploma or after examination.

Oregon.—A certificate on the diploma of a college "in good standing," or after examination by the State Board of Medical Examiners.

Pennsylvania.—A license issued after examination before one of the State Boards of Medical Examiners: Act of May 18, 1893; takes effect March 1, 1894. Diplomas will thereafter confer no right to practice.

Rhode Island.—No legal requirement.

South Carolina.—A certificate of verification of the diploma of a reputable medical college. An Act of December 24, 1890, abolished the State Board of Medical Examiners created by the Act of 1888 and under which the diploma conferred no right to practice.

South Dakota.—A license issued by the State Board of Health after examination. Diplomas confer no right to practice.

Tennessee.—A license on the diploma of a college "in good standing," or after examination by the State Board of Medical Examiners.

Texas.—A license issued after examination by a District Board of Medical Examiners. Diplomas confer no right to practice.

Utah.—A license issued by the Territorial Board of Medical Examiners after examination. Diplomas confer no right to practice.

Vermont.—The registry of a diploma indorsed by one of the Boards of Medical Censors, or a certificate of examination by one of the Boards.

Virginia.—A license issued after examination by the State Board of Medical Examiners. Diplomas confer no right to practice.

Washington.—Similar to Virginia.

West Virginia.—A license on the diploma of a reputable college, or after examination by the State Board of Health.

Wisconsin.—The indorsement of a medical diploma by the censors of either of the State or County medical societies.

Wyoming.—The record of a diploma with a registrar of deeds.—*J. A. M. A.*

## A STUDY OF TRIONAL.

Dr. Beyer (*Archiv. fur Psychiatric*, Bd. XXV. Hft. 2), says:

Among the new hypnotics, trional, since its first therapeutic employment by Barth and Rumpel in the Hamburg Hospital and by Schultze in the Psychiatric clinic at Boon, has constantly gained ground in the estimation of the physicians, all of whom praise its hypnotic properties, although as yet undecided in regard to the more special questions as to its application. Supported by the numerous observations made for a long time at the Psychiatric Clinic of Strassbourg, including personal observations in sixty cases in the female division, it is now possible to sift the material collected up to this time in eight publications, so as to determine the special and general indications for the use of trional.

When administered in sufficient doses, trional almost always produces a feeling of sleepiness, which soon results in quiet, dreamless refreshing sleep. The full effect usually manifests itself in the course of half an hour. It is prevented by bodily pains, noises in the neighborhood, and even light—the same conditions which are also apt to interfere with normal sleep. Patients who have already fallen asleep are easily aroused by noises in the vicinity. Horvath attributes his bad results to the crowded state of his hospital wards at Buda Pesth. The duration of the sleep seems to depend, to a certain extent, upon the size of the dose, at any rate, it was found that while smaller doses act rapidly and effectively, the effects persist for only a few hours. After waking the patients feel refreshed, although the disease from which they suffer is not influenced by the hypnotic. If the dose is accurately estimated no after effects appear. The isolated observations of some authors that a single evening dose exerts an influence on the second night could not be confirmed in our cases of mental diseases. On the contrary, our experience like that of others has taught us, that discontinuance of the remedy, whether intentionally or in consequence of refusal of the patient to take it, or its secret replacement by some indifferent powder, or frequently diminution of the dose, had an unfavorable effect upon the sleep. A slight cumulative action such as has been noted among others by Raimondi and Mariottini seems, however, to exist. Frequently the first dose prescribed fails to act, while if repeated in increased quantity on the following evening it exerts its full effect, and during continued use of the remedy it was often possible to reduce the dose, provided that there was no change in the symptoms.

We can, therefore, coincide with Bries' suggestion to begin with a dose somewhat more than the medium size, and then soon to diminish it.

Habituatian to the remedy has not been observed thus far and we found ourselves necessitated to increase the dose only under certain circumstances, especially excitement, as for instance at the time of the menses. Its withdrawal after protracted use has never had any other consequences than return of nocturnal restlessness, if the patient did not regain normal sleep by reason of the occurrence of recovery.

Various authors have attempted to employ trional as a sedative remedy during the day, but the results have not been brilliant. Schultz obtained a moderatively satisfactory result only when instead of several small doses administered morning and evening he gave 2 grms, and Shaefer likewise failed to accomplish anything with 0.5 grm., given four times daily. Boettiger alone obtained good effects from this method, and demands further experiments with fractional doses. In view of what we have observed, although but in a few cases we would admonish against this method of administration.

Trional is a hypnotic and not a sedative. Small doses are ineffective, large ones induce sleep, or a desire for sleep, which is counteracted by day light, unquiet surroundings, etc., so that a very disagreeable condition results. As far as we can see, the good results in this direction have been obtained only in the case of paralytic or demented subjects who are oblivious to such disturbing influences.

As a sedative we therefore always prefer opium, and have found that its use in conjunction with that of trional affords excellent results, if opium is given thrice daily and trional in the evening. In cases where bodily pains interfered with sleep we observed similar success by combination with morphine, which alone would have had a sedative, but not hypnotic effect. When, however, the pains have been controlled by morphine and then trional was administered, a restful sleep ensued.

As regards disagreeable or injurious after effects, we have not noted these after prolonged use, but after employment of large doses and somewhat more frequently than most authors. If a patient after waking does not at once feel refreshed, but complains of drowsiness, a tired feeling of the eyes, etc., this serves as the first warning to us that the quantity of trional prescribed is too large. Furthermore, we observed in several instances marked drowsiness and very noticeable vertigo and staggering, similar to cerebral ataxia, symptoms which have been described by several authors. Actual symptoms of poisoning, such as severe malaise, cyanosis, vomiting gastric disturbances were seen by us in only two cases, in which trional was administered in several doses during the day, although the total daily dose did not exceed the customary limits. In two other cases slight after effects occurred while the drug was being administered in this manner, so that we are therefore inclined to assume that disturbances manifest themselves more readily after several fractional doses than after a single large dose. As a matter of fact, all the symptoms disappeared within a few hours after discontinuing the remedy and failed to return later if its administration was continued in the proper dose.

One of the main points in the administration of trional is the dosage. This explains in many cases the numerous contradictions in the different reports with reference to the inefficacy of the remedy on the one hand, and the unusual occurrence of after effects on the other. Above all, we would emphasize the radical difference in effect between males and females, which has nowhere been mentioned hitherto. If in one case the administration of even 1 gramme is followed by malaise and a staggering gait, while in another 3 grammes scarcely suffice to produce sleep, this circumstance is easily explained if we have to deal in the former cases with a young woman, in the other with a vigorous man. On an average male patients require at least 0.5 and at the most 1 gramme more than females. A second important element in the dosage is the constitution and bodily weight of the patient. After administration of as small a quantity as 0.5 to a hyphotic girl, whose weight was twenty kilo, we noted well marked vertigo. A third point is the nature of the insomnia or psychosis; aside from these factors a number of conditions must be considered which exert some influence if present for a time, even for a number of hours; these are psychical excitement, hallucinations,

menstruation, and the ingestion of food. For example at a time of especially violent excitement, a patient will require a large dose, 2 to 3 grammes, to obtain the full effect, without experiencing ill results therefrom, while later when at rest the same dose would produce disagreeable after effects. Besides this, the effective dose gives comparative little latitude, and quite closely approaches the dangerous limit.

For all these reasons we cannot agree with previous observers who let the dose range from 0.5–3 grammes, fixing the latter as the upper limit. It must again be emphasized that trional demands a dosage accurately regulated according to the sex, constitution, bodily weight, the nature of the disease, and the presence of temporary symptoms, the dose being subject to daily revision if possible. It is frequently advisable to determine the quantity to be used in the evening just before its administration, which is perfectly feasible on account of the rapidity of the effect, and preferable to giving a second dose later in the night. A well estimated single dose in the evening assures almost without exception a good effect.

It remains to consider the main indications governing the employment of trional. Its action is almost absolutely certain in simple insomnia and also in cases of neurasthenia, the initial dose for males being 1 to 1.5 grms., for females 1 grm. and later reduced to 0.5 gms. Similar brilliant results may be obtained in simple melancholia from the same doses, especially in the above mentioned combination with opium. Larger doses are required in mania, but have equally good effects; 3 grammes may be administered to males, 2 grammes to females, the large doses during attacks of especially marked excitement, the smaller during their subsidence, while during the period of convalesence, they may be reduced to 0.5 grm. Trional has a remarkably favorable action upon the hallucinations both in the acute forms as well as in chronic paranoia. The patients, often to their own surprise, slept quietly and undisturbed, even after administration of medium doses 1 to 2 grammes. In delirium tremens, if the dose is accurately estimated, the effect seems always to be developed. In the other psychosis we have not as yet obtained results which would warrant positive conclusions, and the numerous cases in the literature furnish no uniform data, especially since the above mentioned points are not sufficiently noted in reporting the results. Further observations, which should be as specific as possible will be necessary to explain the still uncertain indications for the use of the remedy in paralysis, morphinism, etc.

This much is well established, that trional although devoid of useful sedative properties, may be warmly recommended as an excellent hypnotic; in small doses in simple and neurasthenic insomina, in combinations with morphine in cases of bodily pains, in combination with opium in melancholia, in medium doses in cases of hallucinations, in larger ones in mania. The drug has no specific influence upon the psychosis. The effective dose varies according to the individual and the symptoms, ranging from 0.5 to 4 grammes.

It closely approaches the limits of dangerous effects which sometimes manifest themselves after small doses down to 1 gramme, so that a generally applicable maximum dose cannot be designated. We are even the less inclined to fix the maximum daily dose, since it is our custom to administer trional only once pro die and in the evening. Injurious after effects can be easily avoided and rapidly and completely disappear as soon as the remedy is discontinued. Permanent ill results have not up to this time been observed.

---

MR. SUMMERBOARD—"What are you going to do now?"

Mr. J. Hay Seed—"Jist a settin' this hen."

Mr. Summerboard—While you are about it couldn't you set the rooster, too?"

Mr. J. Hayseed—"Set th' rooster! If that ain't a good one! W'y—"

Mr. Summerboard—"As I was saying, could you not set him for about six in the morning I am tired of being awakened at daybreak."—*Lowell Vox Populi.*"

---

AN illustration of the severity of the times is found in the fact that two London physicians lately advertised in a daily paper, offering $5,000 to a man who would submit to an experimental surgical operation involving some risk. One hundred and forty-two answers were received.

# SOCIETY REPORTS.

## THE LOUISVILLE MEDICO-CHIRURGICAL SOCIETY.

*January 19, 1894.*

[Stenographically Reported by C. C. Mapes, M. D.]

### MICROCEPHALUS — PROPRIETY OF OPERATION.

DR. A. M. VANCE: I asked this lady to bring her baby here this evening to show a typical case of arrest of development of the brain—microcephalic condition—and to bring up the question of an operation which I performed once or twice in this city. This case seems to me to be a typical one of the class which have been operated upon formerly even more than at the present time. I have recently come to the conclusion, more particularly from reading and also from my experience, that craniectomy for microcephalus is an unjustifiable operation, and I have so informed this mother. This child has practically no mind, and is also paralytic. In talking with Dr. J. F. Barbour, who receives a great many foreign exchanges, he told me of a report by some French surgeon who for years has had charge of one of the largest foundling asylums in the city of Paris, who reports eighty-three cases correlated by him and in this report he draws the conclusion that in no case did good result from the operation. In the case I reported some time ago, and also made a continued report,—the patient was about the age of the one before us,—there has certainly been no material improvement from the operation. I opened both sides of the head, allowing a period of several months to elapse between the operations and while the child had no trouble from the surgical procedure, there has been practically no improvement in the condition after almost a year. I would like to hear an expression from the fellows on this subject. The Frenchman I have referred to states that it is entirely a mistake to suppose early ossification is the causative agent in lack of development of the mental faculties; that the brain ceases to grow, and early ossification takes place owing to the arrest of development of the brain substance.

#### DISCUSSION.

DR. J. M. RAY: I have nothing to say regarding the surgical procedure, but I would like to see an ophthalmoscopical examination made of the eye.

DR. A. M. CARTLEDGE: I do not think from what I have read, and what Dr. Vance, who has had considerable experience with this class of surgery, says, that the results justify an operation.

DR. TURNER ANDERSON: I do not see what could be accomplished by an operation in this case. It is the first typical microcephalic child that I have ever seen.

DR. E. R. PALMER: How long has this child been going to see a doctor, and has there been any discharge from the nostrils?

DR. A. M. VANCE: The mother dates the trouble back to an attack of pneumonia lasting for three weeks when the child was about a month old. There was some catarrhal trouble at that time which was attributed to the attack of pneumonia.

DR. WM. BAILEY: Cases like the one before us have generally been regarded as utterly hopeless. I was delighted at the prospect that was offered to the profession in the claims made by those who were operating according to the method Dr. Vance has spoken of, that some good might possibly come to these hitherto hopeless cases. I do not think it has been determined what is the pathological condition here, whether the arrest of brain development is dependent upon consolidation of the cranium and want of development there. I think that it is noticed that the cranium closes sooner in these cases and more firmly; then, again, that there seems to be a failure of development of the brain, so it is a question in my mind whether the trouble is early ossification, or whether a failure of brain development precedes that condition, dependent upon something else that we do not know. I was hopeful when operation was first proposed and reports made by those operating, that improvement would follow. I can readily see how by opening the skull, giving the brain additional room, that temporary improvement would come, and I believe this is the history of some of the cases—that the muscular spasms, that the irritation apparently is diminished for the time being, but I am sorry to learn that there is no better outlook for the operation.

DR. T. S. BULLOCK: Like Dr. Cartledge the only knowledge I have of these cases is from reading, and from this I have come to the conclusion that operative procedure is unjustifiable, and I question very much

whether there is any betterment of symptoms even of a temporary character.

DR. W. L. RODMAN: I, like the other gentleman, who have spoken except Dr. Vance, have never done a linear craniotomy, but I have had several opportunities to do it; in fact, I was called to see this case three months ago, having been asked to see it by Dr. Woody, and declined to operate, I do not see that there is anything to be gained by an operation, and have never believed in it. I have seen it done several times and have been so situated that I was able to follow the history of a number of cases that had been operated upon by Keen and others at Philadelphia. The result in these cases was such as not to encourage me to operate. Two years ago this month I visited Dr. Kerlin, who was then Superintedent of the largest Feeble Minded Institute in the United States, which you know is at Elwyn, Penn. He talked a great deal about the operation. He told me that a number of children in the Institution had been operated upon by Keen and others without improvement. Keen has done more work in this line than any other surgeon in this country or anywhere else, except Lanilangue, who first performed the operation. It is a dangerous procedure as we all recognize, a fair proportion of the patients dying on the table. In view of the fact that it is such a dangerous procedure, and that results have not been as good as we might have expected, I believe the operation is one which will very speedily fall into disuse. It seems to me that it is not based upon good patholooy and I believe the operation has no place in the surgery of the future.

DR. J. A. LARRABEE: This is the fourth case of microcephalus I have seen recently, and I believe this child is in better condition than any of the others. The last one seen was in New Albany, Ind., a child probably two or three months older than the one before us; head measurement 15 inches, while this one measures 16 inches. While in the other cases the attention could not be drawn to anything this child sees without doubt and is attracted by distant objects. The palatine arch in this case is not nearly so high as in many other cases. The vaulted arch of the palate which lessens the capacity of the cranium is much better in this case than in the three others I have alluded to.

In regard to the matter of obtaining relief by craniotomy or by division giving the brain more room: I believe that operation is adapted to some cases where we have a condition opposite to this, and that is of hypertrophy of the brain, by which I mean an increase of the white fibrous tissue crowding out the gray matter of the brain so that it cannot be deposited. I believe in such a case as this benefit might be expected from an operation. But in a microcephalic skull like the case before us, it has simply adapted itself to the brain and I fail to see the necessity for an operation. In the other class of cases the child is forever trying to break its own skull. I have seen cases of this kind where they have endeavored to strike the head to obtain relief; it would seem that if we could take a mallet and break the skull as we would break a cocoanut, it would afford the proper relief. In hypertrophy of the brain, when the skull is divided in *post mortem* examinations the convolutions are found so flattened, the brain is so pressed that you cannot introduce a small instrument between the folds. It seems to me that there is an indication for craniectomy in such a case, and we might hope for relief by it, but as I have already intimated I do not see what hope we have for relief by operation in the opposite condition, like the case before us. From my experience and observation with several of these cases, I believe the best results are obtained by putting such children in a Feeble Minded Institution, where they may be properly cared for. In such an institution some development takes place, and in the case before us I should have more hope by that method of treatment than anything else.

DR. E. R. PALMER: There is one question I neglected to ask, and that is whether this mother ever had a miscarriage?

DR. A. M. VANCE: She has had one miscarriage at the fourth month, and preceding the birth of this child.

DR. C. W. KELLY: I can only voice the opinion expressed by Dr. Bailey so far as closure of the skull upon the brain is concerned; first that there is arrest of brain development, then closure of the sutures. It is evident that there is arrest of development of the brain otherwise there would not be closure of the fontanelle and sutures. If that be true an operation would necessarily not be warranted or justified; certainly I can see no future for operation upon cases of this character.

DR. W. C. DUGAN (Visiting): I have had no experience in this class of work; I have assisted Dr. Vance in one operation, but had no opportunity of following the case to see what the result was. Dr. Cantrell, of Salt Lake City, Utah, some time ago sent me several photographs of a patient he had operated upon by the method Dr. Vance has mentioned. This patient had spastic paralysis of one side. Before the operation there was no intelligence, whatever, but there was certainly great improvement after the operation. However, not enough time had elapsed to justify him in coming to any conclusion, but certainly the spastic hemiplegia was entirely relieved by the operation.

DR. E. R. PALMER: There is a man in this city whom I knew as a boy, and I knew him to be in active syphilis when he married; if he has not a child which is an absolute mate to the one presented here to-night, I never saw two cases of disease that looked alike. The child is now about three year old, and is carried about by its grandfather; it has the same convulsive movements the same strabismic condition, the same characteristic Hutchinson's teeth. The mother gives the history of a miscarriage at four months, just as in the case before us to-night. It is a very common thing for people who live a few miles in the country to come in town and in their "lark" as they call it, contract a case of syphilis, go back home and have some such result follow as we see in this case and also in the case of the clerk I have mentioned. The father of the child presented to-night lived within a few miles of Asheville; of course there is nothing personal in these remarks. The child seems to be well nourished. It has not the characteristic fingers of hereditary syphilis, but it certainly has notched teeth which, however, might occur from ordinary malnutrition; but it is strikingly like the child of the clerk I have spoken of whom I knew to be in active syphilis with early secondary eruption out when he married, and his wife so far as her general appearance goes, is absolutely devoid of any syphilitic manifestations.

If an operation is advisable it would be that the public might be relieved of the care of a child which is unquestionably an incurable idot.

DR. A. M. VANCE: I have very little to say further. It is a subject that ought to be discussed because these children are being operated upon every day, and I do not believe the literature of the subject will bear us out. I believe it is about seven years since the first operation was done and this French surgeon has collated eighty-three cases; he is a man evidently of large experience having had charge of the largest Foundling Asylum in Paris for twenty years, and he states that no benefit is derived from operation. He also makes the statement that he is convinced from his operations, that in many of these cases it is not primarily a bone trouble but it is arrest of development of the brain and ossification takes place as a consequence.

I do not think the history of this case points to syphilis as the cause. I have never heard it brought up before. The fact that this is a microcephalic child does not prove that there is a specific element in the family; on the other hand there is absolutely no history of syphilis on either side.

I do not think I will ever do another operation for a condition of this kind, as I believe it is unjustfiable.

DR. D. T. SMITH: First in regard to Dr. Palmer's position that this is syphilis. That the child may have syphilis of course I am not prepared to deny, but that syphilis can perpetuate or produce microcephalus, or that syphilis has any relation to microcephalus, I am not at all prepared to believe.

As to operation: I agree with Dr. Vance that we have reached the position where we all know that operation promises nothing except that it might to a certain extent eliminate from society this troublesome element.

In reference to the conclusions arrived at by the French surgeon, as quoted by Dr. Vance, who claims that there is an arrest of growth or development of the brain, which causes an arrest of the skull and consequent ossification. It seems to me it would be a very hard thing to prove that such a condition occurs. We know very well that through the entire course of animal evolution, there is a correlation between the growth of all parts. Who ever heard of the bones outgrowing the muscles of the arms, for instance, or the arteries or nerves being to short. The forces are so balanced that whatever causes arrest in development of one, similarly affect the other; so I take it where there is arrest of the brain there must necessarily be an arrest of the skull from the same cause, and vice versa.

DR. T. L. MCDERMOTT: I take it that this condition of affairs may be due to some faulty development of the ovum; for instance in a family of eight children, you will usually find seven robust children and one microcephalic child. You will find a history of a miscarriage connected with it, in which there has been defective development of the ovum, and this may have some bearing upon the case.

DR. J. A. LARRABEE: I am as fond of attributing disease to syphilis as any body can be, and I think I have rivaled my friend Prof. Palmer in attributing many things to syphilis; in fact I am very willing to refer a great many of the ills of the human family to this disease, but I think in this we have a case where the doctor draws too broad conclusions from too narrow premises. We are impressed by the rarity of microcephalic children at least in this country; we are also impressed with the multiplicity of cases of syphilis. There are several points in Dr. Palmer's relation of the cases that I want to call attention to. First he emphasizes the fact that the mother of the clerk's child was entirely free, and has been throughout, from any syphilitic manifestations, yet she gave birth to a child giving every evidence of inherited syphilis. I would like to ask Dr. Palmer how this mother could give birth to a syphilitic child and be entirely free from

the disease herself. Second, if this be true then Dr. Palmer must grant that infection of the ovum took place through the male, without contamination of the mother. Does he so grant?

DR. E. R. PALMER: It is a settled matter that many people are practically immune from syphilis. In reply to the second question, authorities differ, but my own belief which is the one most generally held by syphilographers is that a syphilitic baby has a syphilitic mother. However, many syphilitics in early stages present few or no evidences of the disease and that too where no treatment is instituted.*

DR. J. A. LARRABEE: Another point: Emphasis was placed upon the question of serrated teeth, which is a condition of absolutely no importance in deciduous teeth. Characteristic Hutchinson's teeth are furrowed, notched or grooved, and without enamel; but this condition must exist in the permanent teeth to be of value as a diagnostic point. This mother stated that the child was unable to nurse for three days; it is a well known fact that a child suffering with acute pneumonia cannot nurse, so that this fact has no practical bearing upon the question of syphilis. If the child had had obstructed nostrils at birth and that condition had continued for six or eight weeks, that would be an unmistakable evidence of syphilis, but no such history can be elicited. We have not asked this mother what influences were brought to bear upon her individually. It is a recorded fact that during and immediately after the siege of Paris, microcephalic and idiotic children were born in such numbers that all the asylums were filled. An investigation proved this to be due to the maternal impressions received during the insurrection. This mother has not been interrogated as to what maternal impressions may have been received during the time she was carrying this child.

From our present knowledge of the disease I think the effect of syphilis upon the brain is to increase the growth of the packing or white fibrous tissue, and we would be more liable as a result to have an opposite condition of the head from microcephalus, we would get hypertrophy. I believe this is the position taken by all authorities upon the question of syphilis, but I have never heard it intimated before that microcephalus might be the outcome of syphilis.

* Bergh states (*Hospitalstidende*, 1893, p. 697) that, while it is generally acknowleged that syphilis may be inherited as well from the father as from the mother, it has been doubted that the child may inherit from the father while the mother remains in perfect health without syphilitic taint. Bergh has observed a case which appears to prove the possibility of this condition.

A young prostitute who never had suffered from syphilis was delivered of a female child, who, three weeks after birth, presented evident symptoms of hereditary syphilis (erythema syphil., ulcers in the anal region, coryza). The symptoms disappeared after treatment with calomel. More than six months after the birth of the child the mother came under treatment for recently-acquired syphilis, with indurated chancre, enlargement of the inguinal glands, etc. The child had been reared under circumstances in which it was not likely to acquire the disease, the symptoms being those of inherited, not acquired syphilis; and the fact that six months later the mother was taken ill with the primary symptoms seems to prove that she must have been healthy at the time of childbirth.—ED.

---

**Milk as Drink.**

Milk is an important food and should not be taken as a drink simply. If eaten as the Persians use it, holding it in the mouth until it is thoroughly combined with the saliva to aid in its digestion, as a part of the meal it is all right, taking the place of other food. It requires digestion as necessary as any other food, but, that it may digest, it is first formed into a solid mass—"curd," and is then acted upon like other solids. Unlike water, which requires no digestion, as a drink, it cannot take the place of our special drink between the meals without much taxing the organs of digestion. This principle is well illustrated by the fact that the nursing infant cannot take its food rapidly, as it must pass through many small orifices, sieve-like, the drawing process exciting the flow of the saliva, aiding in the digestion of the milk and the nourishment of the babe. I repeat, emphatically, that it is food, and not a proper drink.

---

IF we would take sufficient time for our meals, chewing our food as much as the circumstances really require, taking as much pains in this matter as the smoker does to light his filthy pipe—worse than wasting time in smoking it—we would have much better digestion, with abundance of time for all real duties. We shall all have time for our meals and for sleep, if we waste no time in useless amusements, or anything not required by actual duty, engaging only in such pursuits as will promote our health and happiness.

PROFESSOR—How long should a man's legs be in proportion to his body? Mr. Lowstand—Long enough to reach to the ground, sir.—*Yale Record.*

# CURRENT LITERATURE REVIEWED.

IN CHARGE OF ELLISTON J. MORRIS, M. D.

THE AMERICAN JOURNAL OF THE MEDICAL SCIENCES

for March. Dr. Andrew J. McCosh contributes the

**Report of Four Cases of Brain Surgery.**

The author confesses that the recent advances in the localization of brain functions have not added to the success in treatment of epilepsy by operative measures and states that the results obtained, so far as cure is concerned, are but little better than those obtained a score or more years ago. While it is true that certain cases of Jacksonian epilepsy have been cured permanently by operation, yet we must acknowledge that operations for the cure of true idiopathic epilepsy have been discouraging. The author believes that most of our accurate knowledge must be derived from the observations of the pathologist and and surgeon, as experimentation on animals has thrown but little light upon the matter. The first case reported by the author is one of extra-dural hemorrhage with convulsions, in a lad of eighteen years, the result of a fall received the night before his admission to the hospital. At the operation the surface of the dura matter under the clot was found roughened, but was not lacerated or apparently injured in any way. It was not opened. No additional clot or sign of fracture could be discovered. The patient had a slight convulsion, limited to the right hand and leg, shortly after the operation; but no further sign of cerebral irritation showed itself and the patient made a rapid and uneventful convalescence. He has been perfectly well ever since, earns his living as a bricklayer, and does not hesitate to go on an occasional spree.

The second case occurred in a boy of six years suffering from extra-dural hemorrhage with convulsions and paralysis, the result of a fall down stairs when he is supposed to have struck his head. On the seventh day after injury he began to have convulsions and the operation was performed on the eighth day. On the fourth day after operation there was a discharge of broken-down brain tissue from the drainage tube and a tendency to hernia cerebri. This however, had ceased on the seventh day and the paralysis of motion and sensation had almost disappeared. At the end of two weeks the boy was out of bed, without sign of paralysis. He has been in good health ever since; he has attended school, is bright at his lessons, and entirely free from pain, convulsive movements, or paralysis of either sensation or motion.

The third case is one of drainage of the lateral ventricle in a man of twenty-nine years, florist by trade, who gave a history of occasional attacks of unconsciousness ever since he was twelve years of age. The author states that the patient, at the expiration of eleven and a half months from the time of operation, continues bright and intelligent, and no convulsions have occurred. He has no headache or tenderness of the cicatrix. His memory is good. He has been intoxicated more than once without bad consequences.

The last case was one of epilepsy in a girl of six and a half years in which there existed a sub-dural organized clot. The child recovered quickly from the operation and showed very little shock. For three weeks following there was no special change for the worse or better. The convulsions continued as before, as did the paralysis. Five months after the operation the child had gained in weight and appeared brighter, but the convulsions had not been modified by the operation; they occurred as frequently and their character had not changed. A slight improvement in the paralysis had, however, taken place. Under the date of January 16, 1894, the author notes "during the past four months the progress of the case has been most interesting. In the beginning of October the convulsions became more frequent, averaging from twelve to eighteen in the twenty-four hours. The patient was again admitted to the hospital for the purpose of inserting gold foil between the dura and the brain. The child, however, had slight fever, and in a few days it was evident that she had typhoid fever. The case was rather severe and protracted. The remarkable fact about it was, however, that from the time the disease was well established, not a single convulsion occurred. The child has now been well for about two months, and during this time she has been entirely free from any convulsive movements. She has grown considerably, and the partially atrophied muscles of her right arm and leg seem to be fuller and stronger, though a certain amount of paralysis still persists."

The author states that he has trephined three other patients for epilepsy within the last few months. All have recovered from the operation, though it is too soon to speak on the results. The mere removal of a button of bone from the skull seems to improve nearly all epileptics for a few months, and it is rather misleading to report on the condition of these patients before sufficient time has elapsed for the disappearance of the amelioration which may be attributed to the operation *per se.*

The paper is illustrated with diagrams showing the position of the trephine wounds.

Dr. Herbert Snow, of London, Eng. contributes a paper on

**The Early Diagnosis and Practical Surgery of Cancer.**

He says, "With the exception of a numerically small congenital group of tumors, which he has classified under a special term, *Blastoma*, and which mostly differ from ordinary cancer in arising spontaneously, malignant new-growths are almost entirely restricted to women above the age of thirty-four, to men past forty. Further, they appear in organs which have fulfilled their func-

tional purpose and are undergoing devolution, as now effete appendages, *e. g.*, the sexual organs of women; or else in tissues whose vitality has become conspicuously impaired, such as the buccal mucous tract of men. Hence we are bound to look with grave suspicion upon any incipient tumor-formation in these parts of the respective sexes; in people growing old; in those whose general health and energies have, from any cause, become markedly undermined." The two items which most prominently demand attention are first, the age of the patient; and secondly the history of the case. In the female mamma, the age of thirty-eight years forms a rough limit, which the author has often found of great practical use. Under that period, there is much probability in favor of the non-malignancy of any doubtful "lump." It may be laid down as a practical axiom, too, that no average species of malignant tumor in the adult ever appears without an adequate and generally ascertainable exciting cause. The patient often gives a history of hard toil, privation, or of especially laborious occupation. Among the last named, laundry work, in the author's experience, stands pre-eminent. When a middle-aged woman comes to the Cancer Hospital with a breast tumor, and says she has been a laundress, he has learned to regard the growth as almost certainly malignant. The author reiterates the statement so oftened made that persistent and early uterine hemorrhage in a woman, who from her age may be regarded as predisposed to cancer, should always induce a prompt local examination. In men, a very considerable proportion show marks of antecedent syphilis; others are alcoholic individuals, who also smoke, both of which practices directly deteriorate the epithelium. Men of the laboring class rarely pay the attention which women do to cleanliness. The mouth in particular is commonly foul, and decayed tooth-stumps are seldom interfered with; hence the natural sequence of epithelial cancer, almost invariably the manifest result of neglect. An enlarged lymph gland in the neck, axilla, or groin occuring in a man of forty, not associated with an obviously septic cause in the vicinity (e. g., suppuration, syphilis, diphtheria) and following no mechanical injury, will almost certainly prove to be an incipient cancer, yet the author states that he has seldom met with one of these distressing cases in which the gland had not been painted for weeks or months with iodine. As an example of the evil results of delay and the reliance of upon certain microscopical indications of no more than merely negative value, the author refers to the case of the late Emperor Federick of Germany. The author is of the opinion that the microscope for diagnostic purposes is of doubtful use.

It is of vital importance always, in the surgical excision of these lesions, at the same time to remove thoroughly all of the dangerous lymph glands in the "infection path;" and this, if possible *before enlargement has been suffered to take place.* In the proper working out of this maxim, combined with early diagnosis, lies all the best hopes of improvement in the cancer-surgery of the future.

Nothing is more pernicious than the custom of witholding opium from the average patient until he or she is worn out with pain. Opium, persistently given from the earliest moment at which there is reason to believe the disease incurable by surgical means, not only materially prolongs the individual's life, but it has often a most marked influence in arresting the progress of the growth. A carcinomatous breast thus dealt with, previously to the stage of ulceration, may often be successfully diverted from a rapidly advancing tumor into that withered "atrophic" induration which permits many years of fairly enjoyable life. With this should be enjoined as passive and vegetative a mode of existence as possible; and to such, careful nursing will materially conduce. Cocaine-hydrochlorate internally administered is a useful adjunct to the opiate treatment. Its advantages are best seen in malignant disorders of the alimentary canal. Iron, arsenic, quinine, tonics in general are useless except as placebos.

Dr. Robert P. Harris presents an account of

**A Double Ovariectomy, Performed Fifty Years Ago,**

by the late Dr. John L. Atlee, of Lancaster, Pennsylvania, upon a lady who is still living and in excellent health. The case has several features of note, viz.: 1. The patient has lived longer after an ovarian exsection than any subject whose case is on record. 2. As far as can be ascertained, she is the first from whom two ovarian tumors were exsected at one operation, in any part of the world. And 3. She was the first subject on which the late Dr. John L. Atlee performed an ovariectomy, out of his list of eighty cases, covering a period of forty years. The reporter takes exception to the term "ovariotomy," which does not express excision or extirpation, and prefers the term "ovariectomy," used in the same sense as "hysterectomy" or "nephrectomy," as the more correct. The report of the operation appeared in *The American Journal of Medical Sciences*, for January, 1844, and is embodied in Dr. Harris' account. The five ligatures used in the operation, having one end cut off near the knot—as was then the custom in amputations and extirpations—were brought out at the lower angle of the wound and secured, and the abdominal cavity was cleansed by sponging. The wound was now closed by seven sewing needles inserted at intervals of an inch, and wound in the figure of 8 form with silk, as in the hair-lip suture, strips of adhesive plaster being placed between them for additional security. The lady made a good recovery, and was only bled once, which was to the extent of ten fluid ounces, eleven hours after the operation, when her pulse rose to 136, but it fell to 120 after the venesection. The patient was remarkably well by the tenth day, with a clean tongue, sleeping well, able to sit up, and to walk several times across her room. Three weeks after the operation, she took a ride of two

miles, and two days later, of five or six miles; and on this date the doctor ceased his regular attendance. The operation was performed without either and lasted forty-five minutes. As the patient was alive to every sensation, she particularly refers to the process of breaking up the adhesions of the right tumor, which she says were five, and the separation of which caused an indescribable measure of suffering. In her after-treatment, she says she had a doctor, or a student of medicine with her, night and day for several weeks, and think they felt her pulse every half hour. She remembers being permitted to walk once across her room at the completion of two weeks; and taking a ride of two miles, a week later. She has led a busy life for half a century, and is described as still "active and sprightly."

In his report, Dr. Harris reviews the history of ovariotomy and presents a table of completed "ovariectomies" prior to that of June 29, 1843, together with a short sketch of the life of Dr. John L. Atlee.

The remaining papers in this issue are: "A Contribution to our Knowledge of Epidemic Cerebro-Spinæ Meningitis," by Simon Flexner, M. D., and Lewellys F. Barker, M. B. (Concluded).

"The Times and Modes of the Introduction of the Exotic Diseases of Children into America," by J. Lewis Smith, M. D.

"A Case of Leukæmia, with rare Lymphoid Growths of Orbits and Parotid Glands," by Thos. D. Dunn, M. D.

"Neuralgia of the Right Cranial Nerve of Sixteen Years' Duration; Excision of the Three Divisions at the Gasserian Ganglion; Death," by J. T. Eskridge, M. D., and E. J. Baker, M. D.

"Comparative Vitality of Men and Women," by Brandeth Symonds, A. M., M. D.

---

IN THE BRITISH JOURNAL OF DERMATOLOGY for March appears an article by Dr. Edward Ehlers on

**Leprosy in Iceland.**

The author states that until the last few years it was believed that leprosy had been gradually diminishing, in consequence of government efforts to exterminate it, and was only to be found in Norway, Iceland, and a few other countries.

Owing to its long incubation, it was supposed that most cases occurring outside these regions had been contracted during previous travel.

Some sporadic cases occasionally seem to occur, but the diagnosis has always been received with doubt. One or two cases were called leprous trophoneurosis, and were supposed to differ from the old type of leprosy as modern syphilis does from the ancient form.

Zambaco Pasha now declares the diseases known as syringmyelia and Morvan's disease, to be nothing more than leprosy—the new terms arising from defective diagnosis, and he apparently proves his points. He goes even farther and declares scleroderma, sclerodactylia, ainhum, morphœa, and local asphyxia with symmetrical gangrene, to be consecutive stages and abortive forms. The author is not unwilling to concede ainhum as a possible form of leprosy, but does not think scleroderma and sclerodactylia can possibly be. He states that a large and flourishing leper colony exists in Iceland, and proposes an expedition to it to obtain proof, negative or positive. The paper will be continued in the next issue of the journal.

Dr. Wm. Anderson reports two cases of

**Morphœa;**

one in a married woman of forty-two years, in whom nothing abnormal was found after excision of the skin, and the latter showing no great microscopic changes—even the induration had disappeared almost completely after excision. In the other case the skin over the mammary gland was affected in a woman of seventy-two years. The thickened part was slightly purplish and over (but in all points separated by a layer of fat from) a scirrhus of the breast. The axillary glands were enlarged and the arm œdematous. In this case, again, the microscopic examination threw little light on the affection.

The same author reports a case of gangrenous cellulitis of the leg. A stoker, forty-two years old, suffering from gangrene of the skin on the dorsum of the foot, exposing the extensor tendons, and with inflammation as high as the patella, the skin discolored and separated from the subjacent tissues by sanious pus. The patient gave a history of the fall of a piece of iron on the foot three weeks before, and followed in two days by inflammation.

Sloughs and gangrenous skin were removed, a number of incisions made for drainage, a hot boracic acid injection made and the limb washed in bichloride solution 1 to 2000. A dressing of lint with chlorinated soda solution was used, and steady improvement took place. Skin grafts were successfully used to complete the skin reproduction.

The author thinks the case a rare one and that the condition was akin to the gangrenous erysipelas of former times.

---

**Migranine.**

Under this name Overlach discribes the properties of a combination of antipyrine with caffeine and citric acid. He considers it a chemical combination of the three substances and after five years experience of its action in cases of migraine and other forms of headache, he has come to regard it as an almost infallible cure, even in the most obstinate cases. It is useful whether given in the premonitory stage or after the headache has fully developed and it is seldom that more than one dose is required. The dose is 1.1 gm. to be dissolved in water. This quantity contains only 0.09 grs. of caffeine or one-sixth of the maximal dose of this substance. It is recommended that the patient rest awhile after taking the drug, especially in cases of severe migraine.—*Deutche Med. Woch.*

# PERISCOPE.

IN CHARGE OF WM. E. PARKE, A.M., M. D.

## MEDICINE.

### The Treatment of Erysipelas with Pilocarpine.

The credit for the recommendation of pilocarpine hypodermically, in the treatment of erysipelas belongs to Prof. Da Costa. It is the custom of the author to inject daily one-sixth of a grain of pilocarpine, and in order to maintain the physiologic effects of the drug, to administer besides from fifteen to thirty minims of the fluid extract of pilocarpine thrice daily. Under this treatment, the temperature, as a rule, soon declines and the exanthm speedily disappears. This treatment is applicable in properly selected cases. The manner in which the drug acts is not known. —A. Ashner in *Coll. Clin. Record.*

### Indications for Treatment of Angina Pectoris.

Dr. J. Burney Yeo, summarizes the treatment of angina pectoris, as follows:

1. To maintain or improve, when defective, the general nutrition; to avoid all strain, physical and emotional, and to relieve cardiac feebleness and excessive effort.
2. To relieve dyspeptic conditions and flatulent or fecal distentions of the stomach and intestines.
3. To forbid the habitual consumption of agents which may exercise a tonic action on the heart, such as tea, coffee, alcohol, tobacco, etc., or that which may introduce or develop toxines in the alimentary canal.
5. To avoid and remove all gouty and other blood contaminations.
5. To give such tonic remedies as may improve the cardiac tone and lessen existing tendency to cardio-vascular degeneration.
6. To relieve the paroxysmal attacks by sedatives and stimulants.—*Boston Med. and Surg. Journal.*

### Burns.

The most exquisitely painful burns are assuaged in a few moments by an application of cocainized campho-phenique, after the following formula.

℞ Cocaine in hydrochlorate.....grv.
Campho phenique
Olive oil.....āā ℥ss

M.—Rub up the cocaine and campho-phenique, and add the olive oil.

A man whose hand had been torn and badly burned by an electric discharge, the pain of which was so severe, that he fainted twice before the dressing could be applied, expressed himself as absolutely without pain in less than one minute after the application.—*Med. Review.*

### Guaiacol as an Antipyretic.

Gualacol has been, and as is well known as a substitute for creasote in a large number of cases of pulmonary disease, where that drug was indicated, and so far as we know, has given so much satisfaction that it bids fair to supplant creasote in the treatment of many of these affections. Within the past few months the profession has begun to recognize the fact that it possesses other powers than those of an expectorant and antiseptic, or stimulant of the mucous membrane, and a number of prominent physicians have employed it for the reduction of high temperature.

Two of the most notable contributions which have been made upon this subject—the clinical lecture of J. M. DaCosta, and the interesting paper of Rabillard—are particularly worthy of note. In both these instances these clinicians used the drug externally upon the skin of the thigh, abdomen or chest, either by means of rubbing, or by painting it on with a camel's hair brush. After it was applied to the skin it was thought advisable in some cases to place an impermiable dressing over it in order to prevent evaporation. As a result of the application of 20—50 minims of guaiacal in this manner, it has been found that the temperature of malarial fever, typhoid fever and pneumonia rapidly falls as much as seven degrees in the course of an hour or two. DaCosta asserts that this rapid reduction of temperature is not accompanied by any marked disturbance of the nervous system, or any evidence of collapse, not even by a very profuse sweat; neither does there appear to be a very active chill, although sometimes slight dullness is experienced. The drug does not seem capable of holding the temperature down for any length of time, but it has been found perfectly safe to employ it as often in the twenty-four hours as is necessary to prevent pyrexia appearing with severity. DaCosta suggested that in many cases it may take the place of the cold bath as far as the reduction of the fever is concerned; but whether or not guaiacol on further use proves to be a valuable antipyretic, we are sure that the therapeutic results obtained by the cold bath cannot be substituted by this means of treatment since the cold bath undoubtedly exercises a therapeutic effect over and above that exercised by guaiacol. We do not wish to be understood as stating that Dr. Da Costa believes that the cold bath should not be retained. He simply suggests that guaiacal be employed in its place, when because of the lack of attendance, the bath treatment cannot be carried out, and because he believes that guaiacol is preferable to the antipyretics derived from coal tar in the reduction of temperature. In the treatment of hectic fever of tuberculosis J. Solis Cohen and others

have found this drug of equal value. It may be painted on the chest in the area occupied by the pulmonary disease, but it is said to be contra-indicated in cases in which there are hemorrhage or well-developed cavities.—*The Therapeutic Gazette.*

## SURGERY.

### Chloride of Ammonium in Cystitis.

Dr. G. Carrie, of Blossom Hill, Va., states that he has had excellent results from pulverized purified ammonium chloride, taken three or four times in the twenty-four hours, preferable when the stomach is somewhat empty, each dose to be followed immediately by a half globlet or a globlet of pure cold water. In the following condition the drug has given most satisfactory results in every instance: Cystitis dependent upon stone in the bladder; stricture; hypertrophy of the prostate; deposits of urates, etc.; gonorrhœa, both male and female; cystic irritation from uterine diseases or menstrual disorders; malarial effects; masturbation; early pregnancy; simple urethritis (traumatic) in newly married women; cystic and renal sequelæ of *la grippe*. In the majority of cases it was simply surprising to note the rapidity with which the urine was cleared of bladder mucus, blood-corpuscles, pus-corpuscles, urates, phosphates, etc., the distressing symptoms disappearing therewith; and in no case did the salt occasion any gastric or other disturbance, when taken as ordered.—*Virginia Medical Monthly.*

### A Means of Lessening Pruritus in Cases of Urticaria.

Dr. C. Pacaud (Sillans) has observed that the intense pruritus of urticaria, in children as well as adults, subsides almost instantaneously under the application of lemon-juice. As lemons are to be found everywhere, the method indicated by Dr. Pacaud is obviously a very practical one. For our own part, we are inclined to think that the application of vinegar would be just as efficacious; and we may point out that the soothing effect of acid substances in general (plain or aromatic acetic, dilute hydrochloric acid, etc.,) on pruritus, from whatever cause, has long been recognized.—*North American Practitioner.*

### Sanborn (G. H.) on Adpendicitis.

Conclusions are:

1. That in all cases the physician is concerned only in the early recognition of the disease, the subsequent treatment to be left to the surgeon.
2. That the catarrhal or mild form of appendicitis may be considered the only medical form of the disease; and delay in operating may be encouraged to a reasonable extent.
3. All cases of appendicits which, at the end of thirty-six hours from the beginning of the attack, show signs of increasing disease, should be operated on.
4. That the majority of so-called recoveries, treated medically, are not recoveries in the full sense of the word, but simply a respite which enables one to settle worldly affairs, and take out a life-insurance policy, in anticipation of a fatal termination.
5. The early surgical treatment of appendicitis enable us to avoid in every case uncertain results of a spontaneous cure, the d anger of recurrent attacks, and the often fatal general peritonitis in apparently mild cases.—*Brit. Med. and Surg.*

### Catarrhal Otitis.

Dr. H. N. Spencer, of St. Louis, in the *International Medical Magazine*, says: "In children, where we may not be able to use the post-nasal spray, the head should be held well back and an injection of the fluid through the nostrils should be made by means of a dropper or an opened-mouth syringe. Such a solution as the following might be employed:—

℞ Sodii biborat.....gr. v
Tinct. benzoin. co.....mx
Glycerin.....mxx
Aquæ.....q. s., ad. ʒj.—
M.

"Two or three drops of pure olive oil may be applied after this, or an oleaginous solution composed as follows:—

℞ Menthol.....gr. iij
Camphor.....gr. v
Benzoinol.....ʒj.—
M."

## ARMY AND NAVY.

U. S. ARMY FROM MARCH 4, 1894, TO MARCH 10, 1894.

Leave of absence for one month is hereby granted Captain R. B. Ball, assistant surgeon, U. S. Army, Fort Monroe, Va.

Captain R. W. Johnson, assistant surgeon, U. S. Army, will proceed to Fort Monroe, Va., for temporary duty, during the absence, on leave, of Captain R. B. Ball, assistant surgeon. Upon the return of the latter from leave, Captain Johnson will return to his station, Washington Barracks, S. C.

First-Lieut. Charles Wilcox, assistant-surgeon, U. S. Army, is relieved from temporary duty at Boise Barracks, Idaho, and ordered to return to his proper station, Pnesido, of San Francisco, California.

Leave of absence of one month is granted Major Timothy E. Wilcox, Surgeon, U. S. Army.

The leave of absence granted Major John D. Hall, Surgeon, U. S. Army is extended one month.

Leave of absence for four months to take effect on or about August 10, 1894, is granted Captain Henry I Raymond, Assisstant Surgeon.

Major John Van. R. Hoff, Surgeon, U. S. Army, is hereby assigned to the charge of the office and duties of the Medical Director. Headquarters Department of the East, during the temporary absence of Colonel Joseph R. Smith, Assistant-Surgeon General Medical Director of the Department.

## NEWS AND MISCELLANY.

Dr. Thompson S. Westcott has been elected Attending Physician to the Methodist Episcopal Hospital in Philadelphia, vice Dr. F A. Packard, resigned.

### The Association of Military Surgeons of the United States.

The fourth annual meeting of "The Association of Military Surgeons of the United States," will be held in Washington, D. C., May 1st, 2nd and third, 1894.

This National Organization is composed of Medical officers of the U. S. Army, U. S. Navy, National Guard of the United States, and the Hospital Marine Service—in whose service are many of the most celebrated and distinguished surgeons of our country. A brilliant and able literary programme will be presented. The afternoon of one day will be set apart for an object lesson from the "Manual of Drill," by the Hospital Corps. The evenings will be given up to social entertainments. There will be about five hundred delegates in attendence.

GEORGE HENDERSON,
*Chairman Committee of Arrangements.*

### American Medical Association, San Francisco, Cal.

The committee of arrangements has secured Odd Fellow's Hall Building Corner Market and Seventh streets, for the meeting June 5th, 1894.

Assembly Hall, for the general meeting, has a capacity of 1,500; the twelve smaller halls for section work, range in capacity from 500 downward, with committee rooms adjacent.

The engagement carries three of these rooms on Monday for accommodation of associate organizations, as that of the editors, colleges, etc.

The banquet room on the ground floor, 65x95 feet, will be devoted to exhibition purposes, for which it is admirably adapted, and has been secured for the entire week that exhibitors may have Monday in which to place their goods, and Saturday in which to remove them. Nearly half of the space is already taken, and others who desire to make a display of their goods under the most auspicious circumstances ever presented on the Pacific coast, should lose no time in applying to chairman for space.

Headquarters for the Association have been located at the Palace Hotel cor. Market and Montgomery streets, only four blocks from the place of meeting. Here we have "Marble Hall," 30x40 feet, as a registration room where work will begin on Monday, and parlor A for committee work.

The following hotels, centrally situated and convenient to the place of meeting, have quoted special rates for members and their families, which will apply during the entire stay of the guests, who should upon registering, signify that they are in attendance upon the meeting of the Association.

The rates quoted are for single persons, the variation depending upon the size, situation and appurtenances of the rooms, as single, en suite, with private bath, etc. Special arrangement will be made for families or parties on timely notice.

Some of the hotels entertain upon the American plan only; some upon the European plan only, and some upon either plan to suit guests.

Palace Hotel (headquarters) American plan (rooms and board) $3.50 to $5.50 per day; European plan (rooms only) $1.50 to $3.50 per day. Baldwin Hotel, American plan, $3.50 to $5 per day; European plan, $1 to $3 per day. California Hotel, American plan, $3.50 and up per day; European plan, $1.50 and up per day. Lick House, American plan, $250 and up per day; European plan, $1.00 and up per day. Occidental Hotel, American plan (only) $2.50 and up per day. Hotel Pleasanton, American plan (only) $2.50 to $5.00 per day. Russ House, American plan, $2.00 to $3.50 per day; European plan, $0.50 to $2.00 per day. Grand Hotel, connected with the Palace by a glass-enclosed bridge across New Montgomery street, European plan only, $1 to $2 per day.

In addition there are many other hotels, boarding houses and restaurants contiguous to the place of meeting, where one can be made happy and comfortable at less cost.

Post office, Section R., is located in the Palace hotel on the office floor adjacent to the Registration room, where members can receive all mail matters by having it so addressed.

More anon,
R. W. PLUMMER, *Chairman.*

RED GLASS is to be tried in one of the small pox pavilions at North Brother Island, New York, in order to test the value of the experiments made by Drs. Lindholm and Vinsen of Bergen, Norway, who claim that the pitting of small pox patients is due to the sensitiveness of the skin to violet rays of light.

AT A SALE of unredeemed pledges at a London pawnbroker's, there was purchased the casket in which the freedom of the city of London was presented to Jenner on the 11th of August, 1803, for "his skill and perseverence in the discovery of, and bringing into general use, the vaccine inoculation."

## ORIGINAL ARTICLES.

### TREATMENT OF ERYSIPELAS WITH HYPODERMATIC INJECTIONS OF CARBOLIC ACID.

J. McFADDEN GASTON, M. D., Atlanta, Ga.

Having noted in the discussion of a case of erysipelas, before the Louisville Clinical Society, that Drs. A. M. Vance and J. M. Krim lay great stress upon the local application of carbolic acid, I feel prompted to give my experience confirmatory of its efficacy when used hypodermatically in this disease.

About twenty years ago my attention was directed to this remedy by a report of successful results in an English medical journal, and, finding that it fufilled all that was claimed for it, I have employed it frequently in all the various forms of erysipelas which have come under my care. It has been attended with invariable good effects in promptly arresting the progress of this disease. In some cases no other treatment has been employed, so as to test its virtues without resorting to constitutional measures, and the effect has been entirely satisfactory.

I recall only a single case during all this period, which did not yield to this treatment and that was in a patient, to whom I was called in consultation, at an advanced stage of erysipelas, involving the entire scalp, accompanied with coma. As an offset to this, I have frequently employed the carbolic acid hypodermatically when the scalp was partially involved in erysipelas, with complete relief.

I am reminded by the allusion of Dr. W. H. Wathen, during the same discussion, to complications of delivery at term with erysipelas, of a case in which there was a face presentation, requiring prodalic version and followed by erysipelas of the genitalia and the hypogastric region. The injections, hypodermatically of carbolic acid in various portions of the area affected was crowned with complete success.

The formula employed by the original reporter, when name is not remembered, was a solution of carbolic acid in dilute alcohol. But this was modified by me afterwards, and I have used during the past ten years the following:

℞ Carbolic Acid..... ʒ i
Glycerine..... ʒ iii
Distilled water..... ʒ iv

Mix and inject hypodermatically one syringeful in each portion of the size of a hand, daily.

It will be observed that this is a 12½ per cent. solution, and only in a few cases has any local irritation resulted from the injection.

When the thickened and hardened condition of the skin has rendered it difficult to introduce the needle, I have selected points on the border of the dermatitis to make the injection, so as to reach the areolar tissue beneath the skin. There is little pain connected with it. I am convinced that many cases of erysipelas will yield to this treatment; but it does not preclude the resort to any internal means which may be indicated, and when the extent of surface involved is large or the febrile condition is great I have used internal remedies.

The best effects have been secured by giving at the outset calomel, followed by Epsom salts in senna tea, to procure free

evacuations from the bowels. After purgation I have given 25 drops of the muriated tincture of iron every three hours until an ounce is taken. In some cases chlorate of potash in 10 grain doses has been combined with the iron, especially when there is a tendency to the phlegmonous form of erysipelas.

But when I am called early to the case and find the erysipelas circumscribed, I rely upon the hypodermatic use of the formula given above and rarely have any occasion to employ other means of cure.

An instructive case was presented a few years after commencing the use of this remedy. Having treated an acute case of erysipelas in the family of a man, he informed me that he was subject to a periodic recurrence of this disease in his feet and legs, every Spring. I had an understanding with him to give me notice of the next appearance, with a view to test the remedy in this chronic state. In the course of time I was called, and found a well developed case of erysipelas on both legs, extending up to the knees. The carbolic acid was used hypodermatically in two places on each leg, and repeated on two successive days, without any other treatment. All traces of the disease disappeared, and during five years subsequently there was no return of the disease, nor did there seem to be any threatening of future trouble.

In this instance the elimination of disease was complete and indicates a specific action of carbolic acid in the cure of erysipelas.

The influence upon the system of such an injection is general and not confined to the immediate location of the puncture, so that it may be considered as a constitutional impression of the remedy. Some caution is requisite against an undue quantity of this solution of carbolic acid being used on one occasion, but a toxic influence is manifested. But I have repeatedly introduced a syringe-full of the solution in four different places, without producing any untoward effect, and hence it may be allowed that this quantity, distributed over an area of four hands' breadth, is entirely safe. It is also found proper to repeat the injections daily for three days, but I have never had any occasion in which it was requisite to continue the treatment for a longer time. My patients have generally been so far relieved within three days or less time, as to dispense with further injections.

## LAVAGE IN THE TREATMENT OF DISEASES OF THE STOMACH.

PHILIP HURT STRAUSZ, M. D., Toledo, Ohio.

I have noticed, from time to time, articles in our medical journals on the treatment of dyspepsia, and have been surprised at the want of mention of one of the most important adjuncts to the treatment of almost all forms of stomach difficulty, viz., Lavage, as practiced by Dr. Dujardin-Beaumetz, of Paris, France.

I have for several years paid special attention to diseases of the alimentary canal and have given much thought to washing the stomach, having in the last five years washed every case of chronic stomach trouble that has presented itself to me for treatment. In the first place it seems to be the only rational means we have for a certain diagnosis of the character of disease the patient may have, for as all know the term dyspepsia conveys little if any meaning, being only a symptom of an organic disease.

I would like to give some of my experience with the straight tube. I always have my patient present him- or herself, from four to six hours after having eaten, when I usually find the stomach free of all food. If, after trying to introduce my tube there be much reflex irritation, I at once introduce about one ounce of a saturated solution of Calcium sulphide to reduce this state, which it does. After having filled the stomach about one-third full of plain water, at a temperature of about 112° F., I syphon this first water off into a clean vessel, saving this result for diagnostic purposes. I continue to use plain water during the first sitting 'til the water returns through the syphon as clear as when introduced into the stomach. I then make my examination of the first liquid and usually diagnose my case from that.

I have treated many cases of ulceration of the stomach, with the most gratifying results, both to the patient and myself, by using in these cases first a solution of resorcin, washing thoroughly with this aseptic water, after which I use about ʒi of Bismuth subnitrate to a pint of water, letting this water remain in the stomach about two minutes and then syphoning it off, thereby coating an aseptic sore with the Bismuth.

In atonic dyspepsia, when the muscular walls are so much relaxed as to hardly perform any function, the continued ingestion of hot water seems to impart to them a stimulation and, with the addition of large doses of Strychnia sul., will regenerate an almost worn out stomach.

I have had case after case of catarrh of the stomach, where the mucous glands have been stimulated to such an extent that their secretion overrides all others, and where I have been able to syphon at my first washing not less than one pint of a thick, vicid mucous, so heavy that it sinks to the bottom of the receptacle like lead. Almost complete relief is given in these cases by the employment of an antiseptic wash, followed by the use of arsenate of Copper in $\frac{1}{100}$ grain doses each morning, taken in a glass of hot water. This form of dyspepsia is the most common and persistent that will come to the physician, and requires great patience on the part of both physician and patient.

Another very prevalent form of dyspepsia is what is known as putrid indigestion, where the patient's stomach fills with the accumulating gasses of putrefaction and causes not only pain to himself, but disgust to his friends who are unfortunate enough to be associated with him. In this form it has been my custom to use a solution of permanganate of potash until the reflex shows the entire absence of organic matter in the stomach which will occur after the injection of about one gallon of water.

I could go on and mention the different forms of disease of this most important organ treated by lavage with proper medication, but hardly think it worth while, as I leave it to the physician to use his own judgement as to what is required in each form. What I wish to impress is that the unpopularity of this method of treatment of disease of the stomach is due to the fact that almost all practitioners use the same solution in every case that presents itself, whereas each form of dyspepsia requires a separate and distinct form of medication as does any other disease. If the physician will first of all diagnose his case, his own knowledge of medicine will indicate the treatment required, and I can assure him, after an experience of many years, that the results will prove satisfactory.

---

**Special Exercise to Correct and Prevent Constipation.**

Friction, rubbing, or massage over all parts of the abdomen two or three times per day by the patient himself, or less frequently by a good magnetic operator will help promote vital action of the bowels. If not convenient for the patient to walk or ride for exercise, he can secure the advantage of both in large degree by the following exercise taken in his room:

Standing with the feet well apart to broaden your base, bend or flex the lower limbs at the knees and extend the same about twice a second, or one hundred times a minute, for several minutes at a time, three or four times a day, and at the same time twist or turn the body above the hips first to the right and then to the left as far as you well can, resting the hands upon the hips or allowing them to hang by your side. At each turn of the body toward the right or left you will bend the knees about three or four times. You thus use chiefly the flexors and extensors of the thighs, and the rotating muscles of the trunk. The motion of the body is meanwhile up and down, and the motion of the chest and head is alternately to the right and left. To facilitate the turning of the body, the heel of the limb opposite the one on which you rest, as the body sways from side to side, may be raised so as to allow the limb to turn upon the ball or toe of the foot. To get the best effect of this exercise the head must be kept well up, the shoulders back and the spine erect during exercise. The bowels may generally be allowed to rise and fall with the body, but at times it is well to exercise the diaphragm by endeavoring to draw up beneath it the liver and viscera of the abdomen.—Dr. Dutton, in *Jour. Amer. Health Society.*

# COMMUNICATIONS.

## REMOVAL OF THE GASSERIAN GANGLION AS THE LAST OF FOURTEEN OPERATIONS IN THIRTEEN YEARS FOR TIC DOULOUREUX.*

W. W. KEEN, M. D.,† AND JOHN K. MITCHELL, M. D.,‡

MEDICAL HISTORY BY DR. MITCHELL.

J. T. K., aged forty-one years; married; dental surgeon. Until his thirtieth year he was in excellent health, and had no indications of any tendency to neuralgic disease. The history was in every way a good one up to the beginning of the present trouble, with the exception that he was born after a labor prolonged for four days.

The patient was small but strongly built, though when first seen in a much reduced state physically, and in a condition of severe nervous and moral prostration. There is a marked difference in the color of the two eyes, the right one being brown and the left blue.

In 1880, without any previous warning, he had a sudden attack of violent pain in the right upper jaw, nearly limited to one tooth. This came on during a meal. The tooth was extracted, but the pain continued in the socket from which the tooth was withdrawn until this healed, when the pain began in another tooth, and the process was repeated until three were drawn. Only one of these, the twelve-year-old molar, which had been filled some years before with tin and amalgam, was found in an unhealthy condition. The roots were perfectly dry and the foramen very much enlarged. Some portions of the alveolar process, it is said, came away with the extraction of this tooth, and this was also dry and unhealthy-looking. The following summer a portion of bone of that alveolar margin was removed for necrosis. After the parts were healed the pain ceased, with the exception that occasionally at the side of the molar tooth a sharp pain, like that of an exposed nerve, was felt if the part were touched. This also disappeared during the following few months.

In February, 1881, while washing his face, the patient felt a pain shoot through the infra-orbital region, which increased in severity from day to day until he had to stop work on account of it. After a deal of suffering, his physician, Dr. Kirk, of Fox Chase, brought him to Dr. R. J. Levis, who after examination thought that the pain was caused by the gums contracting so as to press tightly upon the nerve radicles. This he attempted to remedy by cutting loose the gum from the bone for the whole depth of the process, both on the palatal and buccal sides; but no benefit was felt from the operation, and later Dr. Levis cut down upon the infra-orbital nerve at the foramen and removed a small portion of the nerve, again without succeeding in relieving the pain.

After suffering great agony for some weeks, Mr. K. was advised to have his upper teeth extracted. In the attempt to do this the eye-tooth was broken in the gum, and the root could not be removed until Dr. Garretson extracted it some time afterward, and in examining the mouth found a necrosis of a portion of the upper jaw, which he removed.

For a short time the pain in the face was much better, but became finally so very severe in the region of the infra-orbital again, that Dr. Garretson cut down upon the infra-orbital nerve and removed all the portion interior to the foramen, finding the nerve intact. This was in September, 1881.

No further operation was done until February, 1883. Mr. K. matriculated in the Philadelphia Dental College in 1881, but on account of his sufferings was obliged to desist from work. In the spring of 1883, pain returned in a small area in the side of the upper jaw, and the sixth operation, undertaken by Dr. Garretson, re-

* Read before Philadelphia. Co. Med. Soc. February 14, 1894.

‡Physician to St. Agnes' Hospital; Assistant Physician to the Orthopædic Hospital and Infirmary for Nervous Diseases.

moved a portion of the upper jaw, exposing the antrum. The patient had comparative ease until the fall of 1883, when the pain began again, and he was variously treated during the succeeding four or five years without much relief.

In the winter of 1887-88 he suffered dreadfully, and in March Dr. Garretson made a resection of the second division of the fifth nerve on the affected side, this being the seventh operation, but how much of the nerve was removed is not stated.

In March, 1889, the third division of the fifth nerve, back to the foramen ovale, was resected by the same surgeon, with much relief; but the pain soon returned, and the ninth operation was the ligation of the facial artery in 1890. In September of the same year, the tenth operation took place—an excision of the whole upper jaw. In September, 1891, Dr. Garretson did the eleventh operation, by opening, at the patient's request, the inferior dental canal and removing the nerve as far forward as the foramen.

From each of this frightful series of operations the patient experienced some temporary relief, with the exception of the one or two otherwise noted. On admission to the Orthopædic Hospital and Infirmary for Nervous Diseases, in May, 1893, he was suffering from three or four paroxysms of severe pain a day, for the relief of which he was taking half a grain of morphine twice a day, and more if the attack was too painful to bear. The right face was sunken, wasted, and seamed with the scars of the several operations; and, in spite of the removal or cutting of the various branches of the fifth nerve, the upper part of the face was still very sensitive, so that to twitch the eyelid, or scratch the right eye, would cause a violent outburst of pain in the *lower jaw*, running forward to the corner of the mouth.

An area of diminished sensation was found upon the outside of the cheek extending from the lobe of the right ear throughout the distribution of the fifth nerve, under the right eye to the median line of the nose and to the median line of the lips. Sensation was not lost in this area, but much diminished, and heat and cold were perfectly distinguished throughout the region.

A few days after his admission a small corneal ulcer was observed upon the outer side of the right eye, midway between the pupillary margin of the iris and the periphery.

The first week in June, Dr. Weir Mitchell and Dr. Keen had a consultation and decided to examine the condition of the inferior dental nerve, in view of the possibility of its having regenerated as to cause the pain which centred in the lower jaw. The severity and frequency of the paroxysms by this time had somewhat diminished from those which occurred on his admission to the hospital, but the smallest movement of the tongue against the cheek or lips would cause paroxysms; to open the mouth at all widely, to put a finger against the cheek, would all bring on furious pain. A small portion of the right cheek immediately below the eye was totally anæsthetic to touch, extending from near the middle line on the right of the nose down to and including the ala of the nose and out upon the cheek about one and one-half inches. The right angle of the mouth was capable of very little movement, and the lower eyelid was almost completely paralyzed.

The site of most severe suffering was not at this time at the mental foramen, but about an inch posterior to it. From this point the pain spread throughout the inferior dental distribution.

Removal of the Gasserian ganglion was proposed by Dr. Keen at this time, but as the patient preferred that a new attempt upon the inferior dental nerve should be tried first, Dr. Keen consented to this, and on June 10, 1893, operated.

SURGICAL HISTORY BY DR. KEEN.

An incision was made in the line of one of the old scars near the lower border of the lower jaw. The soft parts being lifted at the site of the mental foramen, a very minute opening was perceived to which the soft parts were adherent by a little thread which may have been a nerve but which tore with slight traction. About an inch and a quarter back of this supposed mental foramen was another quite large foramen corresponding to the focus of pain, from which came out what appeared to be a nerve, which spread out fan-like in the soft parts. This was excised and placed in Müller's fluid. Between the two foramina a button of bone

was removed, but no canal and no nerve could be discovered. I then chiselled away the bone back to and under the large abnormal foramen just mentioned, and found the inferior dental nerve as a thick cord, and followed it backward to the inferior dental foramen. When I seized the nerve to extract it from its bed, although the patient was profoundly anæsthetized he struggled considerably. An inch and a quarter of the nerve was resected from the abnormal opening backward, the nerve being drawn down as far as possible. The upper opening was then closed by a sheet of sterilized gold-foil and the lower portion of the bone, where it had been trephined half through its substance and chiselled backward, was filled with dental cement made of oxide of zinc powder and glacial phosphoric acid. The operation was characterized throughout by exceedingly troublesome hemorrhage, which Dr. K. tells me was characteristic of the former operations also. A dozen strands of silkworm-gut were laid in the wound for drainage, and the wound closed and dressed as usual. He made a prompt recovery. Neither the gold-foil nor the cement has given the slightest trouble.

On the 24th of August he was re-admitted, having suffered much pain again for a month. He describes the pain as being in the right cheek, coming on in paroxysms, induced by eating, talking or any movement of the lips, teeth or cheek. The slightest stroking of the cheek will bring it on. He has no pain if the parts can be kept absolutely immovable. The areas of paræsthesia on the right side of the nose and cheek seemed to be somewhat more sensitive, and this time the pain complained of is all above the level of the inferior maxillary. In the absence of Dr. Keen, Dr. Wm. J. Taylor operated again on the 28th of August, removing the tissues about the infra orbital foramen, with only temporary relief. Early in September the pain had returned as violently as ever, and even large and frequent doses of morphine failed to relieve him. Accordingly he re-entered the infirmary in October, with the intention of undergoing the removal of the Gasserian ganglion.

*Operation,* October 18, 1893, by Dr. Keen. One-thirtieth of a grain of strychnine and a quarter of a grain of morphine were given him just before beginning the etherization. An omega-shaped incision was made, the length of which, vertically, was three inches. One leg terminated immediately in front of the tragus, the other just in front of the junction of the anterior and middle thirds of distance between the external auditory meatus and the external angular process. The temporal artery was cut and this and a few other vessels required ligation. Dr. M. H. Cryer, with the new surgical engine of S. S. White & Co., and a circular saw one and a half inches with a guard, then rapidly and very successfully divided the external table, excepting the two extremities. Here, fearing perforation before the inner table and the rest of the flap were divided, I determined to chisel through. I first chiselled the superior four-fifths of the flap, passing through the inner table with ease, and then chiselled the extremities. At the posterior terminus when I was only giving an ordinary light blow with the mallet, the chisel suddenly penetrated the skull to a depth of perhaps half an inch, and immediately a considerable hemorrhage showed me that the posterior branch of the middle meningeal had undoubtedly been cut. I then chiselled quickly through the anterior extremity, broke the bone and reflected the flap. Here again was an additional trouble, for the anterior branch went through a distinct canal at the anterior inferior angle of the parietal bone, and of course was torn and bled freely as I turned down the flap of bone and scalp. A finger over each artery, however, almost controlled the hemorrhage, and in a very few moments I was able to place a pair of hæmostatic forceps on each. A cut was seen in the dura corresponding in length to the width of my chisel. A small curved Hagedorn needle was then passed first around the anterior branch in the dura, then the posterior branch was caught. The opening in the dura was sutured by catgut. The middle lobe of the brain was then lifted with care and great gentleness from the bone, but this was followed by hemorrhage which might well be called alarming. Lifting up the middle lobe with a spatula, I discovered that it was not, as I had feared, from the middle meningeal ruptured at the foramen spinosum, but that the blood came from the neighborhood of the ganglion. I could not think, with the gentleness I had used, that the cavernous sinus had been ruptured, but

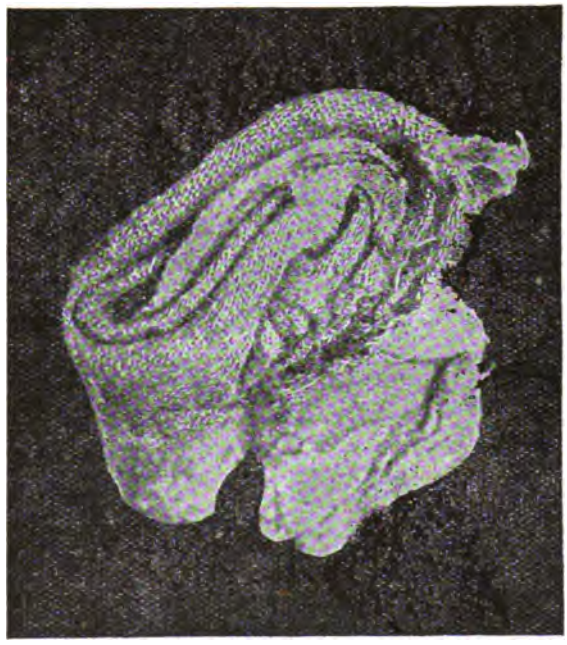
at all events it was too free, not only to allow of removal of the ganglion, but for the integrity of the man's life if it continued. The hemorrhage did not yield to hot water. I packed it twice with gauze which arrested it temporarily, but on removing the gauze it bleed as freely as ever. Accordingly I packed in a considerable piece of iodoform gauze and closed the flap by six retention stitches, with the intention of removing the packing in two or three days and then removing the gang lion. Before packing, the dural wound was closed by a stitch of catgut.

no spots in the eye ground. A field roughly taken shows no limitations.

21st. (Third day.) Since the operation the patient has done well, excepting that he has had, of course, a number of paroxysms of pain. The only evidence of increased intra-cranial pressure due to the gauze, has been a slowing of the respiration down to from six to ten, and a slight aphasic condition. The gauze was introduced on the right side of the head and he is a right-handed man. The highest temperature was 100.8° F.

To-day I opened the wound, which was

FIG. 1



Shows the natural size of the piece of iodoform gauze (37 x 6 inches) packed in the cavity of the skin for three days without harm; seen edgewise.

During the operation he had received in all one-eighth of a grain of strychnine, and an hour after the operation was completed was in bed with warm extremities, a pulse of 80, temperature of 98°, but a respiration of only 8 in the minute but very deep. His color was very fair.

October 20th. His eyes were examined by Dr. G. E. de Schweinitz, who reported as follows: "Irides unlike in color: right brown and left blue. Pupils very small, right smaller; reaction normal. Scar in right cornea. Oval optic disk, paler than normal; veins full and larger than usual; arteries normal. No swelling of disk and

partly united. The small cut in the dura, made by my chisel three days before, was entirely closed, and there was not the slightest evidence of any harm from it. I drew out the gauze very carefully, keeping a stream of hot water playing on it all the time so as to loosen it very thoroughly. I found on measurement that the piece was 37 by 6 inches. (Fig. 1.) It weighed 2½ ounces, and a similar piece, dry, weighed 2½ drachms, showing that it had absorbed 17½ drachms of blood. (Fig. 2.) On withdrawing it I was very fearful at first that the hemorrhage, which was moderately profuse, would again prevent my

doing anything to the ganglion, but on introducing some small hot sponges I was able to overcome the bleeding in the course of a little while by the heat and pressure. Evidently the hemorrhage did not come from the cavernous sinus, nor from the middle meningeal, both of which I found to be intact.

In a few moments I was able to expose the middle meningeal artery and the second and third divisions of the fifth nerve, and see also the little flap of dura which covered the ganglion. I had great trouble in separating the third division from the middle meningeal, as they ran very close together. Moreover, both at the second and third divisions, the slightest touch of the blunt hook, Allis's dissector, scissors, knife, anything, produced the sudden escape of at least a drachm of blood, which obscured the field of operation. Pressure by a small gauze sponge for a very few moments would cause the bleeding to cease, but the slightest manipulation produced its recurrence again. However, after cutting both of these nerves and tracing them back to the ganglion, I tore the little extra-dural sac open, and with the Allis dissector and a small sharp spoon I thoroughly destroyed the ganglion.

The wound was then closed and the usual dressings applied. The patient's condition both throughout the operation and at its end was decidedly better than at the operation on the 18th.

He made a complete and rapid operative recovery and was out of bed on the fourth day, the entire wound being healed. The highest temperature was 101.2.° The aphasia gradually bettered and finally disappeared. He complained bitterly of pain in the head at first, but this soon diminished, especially after the roots of two teeth were kindly removed by Dr. Cryer. Soon after the operation, the morphine being stopped after the first five days, he had the most intense mental depression. In fact, this went to such a degree and assumed such delusional forms that I was doubtful whether it was due to possible cerebral changes from the three days' pressure of the gauze, or to the withdrawal of the morphine alone, and I seriously feared a permanent insanity. Bromides, strychnine, and sulphonal were all used in turn and in full doses, but none of them did him any good. Finally, codeine in ¾-grain doses in the twenty-four hours gave him relief in sleep and checked his delusions, so that in a few days he was quite recov-

FIG. 2.

ered, and since then until the present date, February 14, 1894, has been absolutely rational, free from delusions and pain, and without any desire for his morphine, which on the contrary he loathes after thirteen years of slavery to its use. His eyes were examined by Dr. de Schweinitz, and found to be in the same condition as on October 20th. Glasses were fitted which gave him excellent vision.
(Fig. 3.)

His condition, from a neurological standpoint, will be stated by Dr. J. K. Mitchell.

REMARKS BY DR. KEEN.

First, as to the method of operating. Horsley's operation by a temporal flap, opening the dura and tearing the roots of the fifth nerve behind the ganglion from the pons, seems to be needlessly severe. As between the Hartley-Krause operation, which I adopted, and that of Mr. Rose,* through the base of the skull, I think there is no question that the easier operation is that devised by Dr. Hartley,† and soon afterward and independently by Krause.‡ The table (*vide infer*) shows that thus far they are equally safe. There is much more room for the manipulations by this method than by Rose's, in which one to a great extent works in the dark, through a very small opening. Moreover, Tiffany§ has made the important observation that a deliberate opening of the dura, by allowing the escape of considerable cerebro-spinal fluid, gives much additional room for the intra-cranial manipulations. It will be noticed that the two ends of my incision were placed the one directly in front of the tragus and the other in front of the junction of the anterior and middle thirds of the distance between the external auditory meatus and the external angular process. By examining the skull I have found that this marks, as nearly as may be, the anterior limit of the middle fossa of the skull, and gives, therefore, the widest opening possible for access to the interior. It has the disadvantage that it impinges upon the canal, if there be one, for the anterior meningeal; but anyone accustomed to controlling hemorrhage in the skull should certainly be able to cope with this difficulty, and if the artery,

as is usual, does not run in the canal, no trouble will occur. The advantage of making the flap of scalp and bone, as was done by the osteoplastic resection of Wagner-Wolff, instead of trephining, is, I think, very great, the larger opening being an advantage of the first moment. Moreover, the two ends of the incision should be carried well down, almost to the level of the zygoma, so that the middle fossa will be opened almost completely down to its floor, otherwise the manipulations are much more difficult. The division of the skull by Dr. Cryer with the surgical engine was only moderately satisfactory as to speed. Since then I have had made, at the instance of Dr. E. T. Darby, a drill with two spiral threads which answers the purpose very much better on acconnt of the rapidity with which it divides the bone. Dr. Cryer has figured another drill for the engine, which he says will work more rapidly, but with which I have had no experience. The diagram seems to me to point toward a successful instrument.† In dividing the posterior portion of the bone, it will be noticed that my chisel, by a blow which was not deemed to be too severe, penetrated the cavity of the brain to some extent, but also, what might have been a serious complication and was for a time an embarrassing one, divided the posterior branch of the middle meningeal. This accident has cautioned me as to the use of the chisel. Instead, I should have used Hartley's or some similar osteotome, which, being conical throughout instead of with parallel sides as the chisel had beyond the bevelled edge, would have prevented this accident.

Unfortunately, also, I had to deal with a "bleeder" as was proved by the prior operations, and I presume this was the reason why the hemorrhage was so profuse on the gentle lifting of the temporosphenoidal lobe in the middle fossa. No one with ordinary prudence would attempt to remove the Gasserian ganglion while the field was filled with blood, as fatal injury might be done to the carotid or to the cavernous sinus which lie in such immediate proximity to the ganglion. I think the introduction of the gauze, following the suggestion and practice of Krause in his first operations of this sort, was the wisest step I could have taken. The hemorrhage three days later, when I removed the gauze, was comparatively profuse, but the operation was successfully completed. I was very much surprised, however, when I withdrew the gauze to find that I had packed in so large a piece. It covered 222 square inches, and formed a large wad, which, as it will be observed, had absorbed two ounces and a drachm and a half of blood. It has puzzled me a good deal to account for the absence of symptoms other than the slowing of the respiration and the slight aphasia, as a result of such a large foreign body within the cranium. Possibly a little might be accounted for by the slight yielding of the flap; possibly more by the slight escape of cerebro-spinal fluid by my puncture of the dura; but allowing for all this, the foreign body was a very large one, which must have produced a great deal of pressure. I certainly never introduced so large a piece before, and the fact that four days after it was removed the patient was out of bed with the wound practically healed, showed how rapid was the recovery. That gauze can be left for a long time within the cavity is well known, and has recently been excellently illustrated in a case reported by Dr. Chalmers Da Costa, in which a piece of gauze 8 by 1 inches was retained for thirteen days within the cavity of the skull.

Second, the results of removing the ganglion are, of course, not yet absolutely determined. The first case was operated on by Mr. Rose in 1891.* Since then I have been able to collect 40 cases operated on by the two methods, and the result thus far is as follows: Of the 40 cases, 6 have died and 34 recovered. In none of them has there been any return thus far reported, excepting a partial return in one of the earlier cases of Mr. Rose. In no other case than his first one has there been the loss of an eye, and neither Dr. Tiffany in the 4 cases he has reported, nor I, took the least precaution for the protection of the eye, by preliminary temporary suturing of the lids. The results thus far seem to encourage us very much. If the removal of the ganglion should in time prove to be a final cure in cases of tic douloureux, my own opinion would be that it should be the *first* operation recommended for severe cases, provided that time and experience enable us to diminish the present relatively large mortality. If,

†In a later case at the Jefferson Hospital, Dr. Cryer kindly used this drill for me, and with great advantage.

* British Medical Journal, 1892, i. 261.

however, the pain should return in any considerable proportion of the cases, then, as this is the final and terminal operation, I would certainly advise my patients hereafter to have repeated peripheral operations done, gradually approaching the centre; and the removal of the ganglion, should the pain return again and again, should be the *last* operation. In other words, if the operation of removal of the ganglion proves to be an unqualified success and its dangers are lessened, we should begin with that and not waste time with peripheral operations. If it is only, like the peripheral operations, a temporary relief, then we should begin at the periphery and work toward the ganglion by as slow steps as it is possible to take.

with the condition previous to the operation. He had no spontaneous pain in any part after the operation, and at the time of his discharge the aphasia had entirely disappeared as well as the mental depression.

In the regions supplied by the supra-orbital nerve, sensibility to touch was diminished as far as the vertex upward and forward to the median line of the face from the lobe of the ear and the lower border of the inferior maxilla. The mucous membrane of the lips and cheek on the right side, and the right side of the tongue were also partially anæsthetic. On the right side the sense of taste was entirely lost. The ocular and palpebral conjunctivæ were insensible to touch, but

§ Method unknown. Reference furnished me by Dr. Hinsdale, which could not be verified.

I append a table of all the operations I have been able to collect up to the present time.

REMARKS BY DR. MITCHELL.

After the final operation on October 18th, it was not until the latter part of December, just before his discharge from the hospital, that the patient's mental condition improved so much that a careful examination of the areas of sensation could be made. There was no absolute anæsthesia, except between the margins of the flap of this operation. Sensation to touch was everywhere else preserved in some slight degree. Pain sense was but slightly impaired as compared in the right infra-orbital region immediately about the scar of the operation upon the infra-orbital nerve, there was a small area which was hyperæsthetic.

When last seen, during the last week in December, I found that an area as large as a half dollar, with its center upon the outer third of the right eyebrow, covered a space which was hyperæsthetic to touch though not to pain, and this although he was unable to move voluntarily the muscles above the brow on this side.

Dr. K. has since returned to the hospital, reporting himself as continuing without any pain in the face, but one statement which he makes is certainly curious. During the cold weather when he goes out

he says that he feels as if he had two faces, one quite apart from the other; one of which, the left or normal side, felt the cold and the other did not.

When violent neuralgia marks out with lines of fire the course of superficial nerves, or when by operation we demonstrate the ramification of the tiny twigs to the skin and surface tissues, it is rather the rule than the exception to find some small anomaly in the distribution of the ultimate fibres, as compared with the topography described in the books. Physiological methods of tracing and mapping these nerves are needed, rather than those of the anatomist's dissecting table. In the case here described, the only anatomical peculiarity was the situation of a foramen more than an inch posterior to the mental foramen, giving exit to a nerve of some size, distributed thence on the tissues of the cheek. The foramen mentale was exceedingly small, and through it passed only a little twig, so slender as to make its discovery difficult and its recognition doubtful.

In another patient of mine upon whom Dr. Keen operated some years ago, a different difficulty was experienced in locating this opening. The patient, an elderly woman, had all her teeth removed. The gums and probably the alveolar processes had consequently atrophied, and the foramen was thus brought much nearer to the upper margin of the jaw than usual, and some search was needed before it could be found.

The regeneration that we so commonly find occurs in divided nerves when we do not want regeneration, followed the several nerve sections here, as in other cases. Such a frightful amount of pain teaches an opportune lesson of the desirability of deeper operations in the early course of trigeminal neuralgia. If the neuralgia persist, a neuritis almost inevitably follows, whether brought about by the same irritation which sets up the neuralgia, or, as I cannot but think often happens, set up *by* the neuralgia, the constant pain keeping the nerve over-stimulated and over-full of blood until it passes from active congestion into inflammation. A neuritis, however small, is a bad neighbor. We speak of ascending and of migratory neuritis; but every neuritis ascends and generally descends, too, though it may be only a small spread in either direction. But spread it will—and it is certainly astonishing when we consider the close connection between the nerves of the face and the great centres of life in the brain, that we so rarely see brain disease result from this form of nerve-inflammation.

At the origin of these cases some form of peripheral irritation is often to be found, but by no means constantly. The teeth are usually blamed, and one seldom sees an old case in which they have not been more or less completely removed—because, if they had not caused pain, they might cause pain. The seat of distress is often in a tooth, but do we not always find the sensation of pain referred to the periphery of the affected nerve? I have seen at least one case in which relief of pain that had persisted in spite of palliative operation, resulted from the application of a properly fitting denture. No doubt the restoration of a natural amount of pressure upon the gums and alveoli had something to do with this. In Dr. K.'s case the original cause was in a tooth and destructive processes in the alveolus.

Besides the pain which accompanies these neuralgias, various other troubles may result from the peripheral irritation. One of my patients had had one or two attacks of lesser epilepsy a month, always at her menstrual periods, up to her fiftieth year, when they ceased with the menopause. When several years later, she began to have the trigeminal neuralgia, they returned, and became much more frequent, coinciding with the sharper paroxysms of pain. They disappeared with Dr. Keen's resection of the offending nerve, and have never recurred.

The second and third divisions of the trifacial nerve are much oftener subject to the attacks of tic than the first. It is impossible to assign any reasons other than suppositions for this. The functional necessities of the face and eye require that the nerves which supply them shall be sensitive and acutely perceptive in the highest degree. This gives them a certain susceptibility. Then the position, especially of the second and third divisions, exposes them peculiarly to sources of external hurt, such as irritation, or even infection, from decayed teeth, injury from cold, or from substances taken into the mouth, acting through the lingual branch as well as through the dental filaments.

The ganglion removed has not yet been minutely studied. It certainly would seem reasonable to expect to find in the

centre, after over stimulation continued for so long a period of years, some signs of this excess of action in the nerve cells.

Hodge, in the admirable papers published in 1889 and 1891, upon exhaustion of nerve centres has pointed out the microscopic changes we may expect to find in tired and exhausted cells. They are so distinct that when once acquaintance has been made with them it is not difficult to say of two specimens, "This one came from an animal exhausted by muscular action; this one came from an animal in a healthy condition."

It has been supposed by some authors that the root of the malady lay in an atrophy of the ganglion; but were atrophy to be found, I would rather incline to regard it as a result than as the cause of the morbid condition of the nerve.

## PSEUDO-COXALGIA.*

J. K. MITCHELL, M. D., PHILADELPHIA.

There is not much to be said about hysterical coxalgia apart from its differential diagnosis from true hip disease. The symptoms very closely resemble each other. Hip disease is not a very common form of appearance of hysterical disease of joints. The condition which most often presents itself is hysterical knee-joint disease. I have seen in some years past but two or three cases of simulated coxalgia.

The two differential points on which I should be inclined to lay the most stress are first, that under proper means of examination, even without anæsthesia, motion would be freer than if real disease existed, but this is by no means always true, since often in hysterical troubles a considerable amount of exudate is thrown out about the joint. Secondly, the condition of the local temperature is important, although not positive. If the temperature of a joint, suspected of hysterical disease, be increased and yet there be nothing in the general condition to point to inflammation, this would be an important matter; but it must be said, as was originally, I think, pointed out by Sir James Paget, that if the local temperature be higher at night than in the morning, the case is not one of acute inflammation, but of simulated disease most likely hysterical.

Sometimes there is swelling in these cases, but even if there were neither heat nor swelling, one could not by the absence of these signs alone be certain as to the purely nervous nature of the trouble. I think I should be more inclined to lay stress upon the appearance of the hysterical stigmata, such as tenderness in the spine, ovarian tenderness in females, photophobia, general hysterical manifestations, narrowing of the fields of vision, or changes in the color fields.

As to this later point, Dr. de Schweinitz and I, in a recent investigation, have found so few cases even in typical instances of major hysteria, where the color fields were altered, that it has made me doubt whether the statements, made by the French authors, as to the frequency of occurrence of this change in the eyes, are equally true for this country.

Besides this, in a majority of cases of hysterical disorder, we shall find uterine symptoms and marked tendency to constipation. Perhaps I might mention as a very interesting case of knee-joint disease, in which there was great difficulty in making a diagnosis, one which has already been reported by Dr. Weir Mitchell in his Lectures on Nervous Diseases. The late Dr. Sands, of New York, saw the case early when the joint was much enlarged and quite disabled. His opinion—and we all know it was one entitled to every respect—was that the swelling was entirely outside of the joint proper. Dr. Weir Mitchell saw the girl in consultation, and was also convinced that the case was a hysterical one. The patient, however, went abroad and, in Vienna, was seen by Dr. Billroth and by Dr. Nothnagel, who both were quite certain that the joint proper was diseased, and Billroth went so far as to say that if operation were done the cartilage would be found eroded. On the strength of this judgment, Dr. Sands, with considerable misgivings, opened the joint and found it absolutely normal as to its cartilaginous surface. The swelling which was present was altogether outside of the capsule, and consisted of a brawny thickening of the skin and sub-cutaneous tissues. He closed his wound carefully, and the enlargement, in the course of time, entirely disappeared under general treatment and the patient recovered perfect motion.

# SARCOMATOUS OR OTHER TUMORS WHICH MAY, IN THE EARLY STAGES, BE CONFOUNDED WITH HIP DISEASE.*

DEFOREST WILLARD, M. D., PHILADELPHIA.

Certain tumors originating in the region of the hip-joint, when accompanied by pain in their inception, may easily be mistaken for tubercular bone disease. I can recall but one or two such cases in children, but in adults I have seen a number which have been diagnosed as hip disease before their characteristics were distinct.

A physician who first sees such a case is always at a disadvantage in regard to diagnosis. In children, especially, the history will be very similar to that of tubercular hip-joint disease. A slight blow apparently arouses the disease; then follows pain with increasing limp, tenderness, slight fullness, thickening about the articulation, above or below it, slight limitation of motion in the direction opposite to the side upon which the mass originated; these are the symptoms which would naturally lead one to infer that the more common disease of tubercular ostitis exists rather than the rarer one of sarcoma. An experienced orthopedic surgeon, however, will at once recognize that this partial limitation of motion is frequently found in exceptional cases of tubercular lesion.

Moreover, pain, which increases with the growth of a sarcomatous tumor, is a very constant symptom in the tubercular form; consequently, as I have said, any man is excusable for a mistaken diagnosis in the first few weeks of sarcomatous disease. As the growth proceeds, it is apt to become more localized, that is, its projection is a firm hardened mass in a certain direction, usually anteriorly; while in the tubercular variety, the thickening is more diffused over the region of the joint.

The tumor may or may not be nodulated. Restriction of motion is positive in one direction, usually extension, while flexion is somewhat interfered with by the size of the growth. Tenderness is also limited to a small area, smaller than in the tubercular variety, pain but seldom extends down the inside of the thigh towards the knee. Flexion is usually present to a moderate degree. Abduction or adduction are rarely present. The buttock may be flattened and the ileo-femoral crease shortened as in tubercular hip disease. Instead of atrophy of the limb there is usually swelling or œdema.

During the latter stage the diagnosis is easy. The size, position and character of the swelling is sufficient to mark its nature. Pain, especially in adult cases, does not increase in proportion to the extent of the disease. In one case which I recall, the man suffered exceedingly for two months while the tumor was small, but was almost entirely free from pain during the remainder of its progress (over a year) when the tumor attained enormous proportions. In his case, while the greater portion of the tumor was hard, yet there was numerous cysts and fluctuating points the tapping of which might have been considered for the relief of pain had not the symptoms ceased to be violent.

In one or two other cases which I recall, the cessation of pain, as the disease progressed, was very marked. In one case, already alluded to, the tumor apparently sprung from the periosteum of the neck of the femur, possibly from the bone above the articulation. It had advanced too far before it was noticed, for any operative procedures to give relief, and death occurred from exhaustion. I did not see the case during the early stage, but the history was somewhat similar to that of joint disease; a slight injury, pain after a long walk or after standing, increased shortening of the limb, and gradual interference with the function.

I have a case now under my care which presents very similar symptoms, and yet I believe it to be an early stage of tubercular hip disease in the adult; another case, which is very similar, I believe to be rheumatoid arthritis, and yet I do not accuse myself of ignorance in being unable to positively fix the diagnosis at the first visit. Time alone can solve the problem.

I have a young man under treatment whose difficulty I have recorded tubercu-

*Read before Sec. Orthopedic Surgery, College of Physicians, Feb. 17, 1894.

lar, and yet I have a strong suspicion, on account of the local character of the projection, that it is sarcomatous disease in process of development.

Another case is that of a man forty-five years of age whom I saw in consultation. I found no difficulty in diagnosing sarcoma, although it had been treated for many months, by experienced surgeons, for tubercular trouble. It is no credit to a surgeon who is called in at the late stage to decide as to the character of the tumor.

I saw, still another man past sixty, a consultation case, in whom the pain had been atrocious, but which diminished gradually after the compact tissue of the ilium had yielded sufficiently to permit easy expansion. He had been treated also for many months for hip disease.

I saw to-day, a case of possible malignant disease, in a man thirty years of age, but as there was a history of a year of pain which was characterized as starting at night, and as there was a large but evenly distributed induration about the hip, marked with flexion and abduction, I am strongly inclined to consider it as a case of ordinary hip disease rather than that of commencing tumor.

In another instance where I was called in the country to see a case of hip disease which had existed for many months, a hardened nodulous tumor arose distinctly from the region in front of the trochanter and had attained the size of a child's head. The early history had mislead the attending physician, and as is not infrequently the case, had biased his opinion even when decided sarcomatous appearances were marked later.

Every physician frequently finds himself placed at a disadvantage. Relying upon his first diagnosis, and perhaps relaxing his vigilance, or perhaps failing to re-examine the case for some weeks, he will find, during a more thorough examination, conditions entirely different from those which existed a month previous. Such situations are unpleasant, and are nearly always due to insufficient care; not infrequently to insufficient exposure of the part. I am daily more and more convinced that a large proportion of errors in diagnosis would be avoided if the naked body could be observed and a comparison of the two sides noted.

Sarcomas in this region are usually very malignant in their character. Their growth is slow until rupture takes place, after which rapid dissemination is the rule, with quite possible metastases. The cysts are apparently due to the liquidation of the tumor elements, or to extravasation of blood and serum. Tapping of the cysts is inadvisable except when the pain becomes very great, as protrusion of the mass with hemorrhage follows. In some cases the great vascularity of the tumor with its pulsation may similate aneurism, especially the central round cell sarcomata, the medullary or hematoid cancers.

Few of these tumors are suspected from the beginning and only occasionally is it possible to recognize them early. In order to do this the entire group of symptoms must be surveyed, not merely one particular symptom. In the majority of cases it will be found that although one or two, or perhaps half a dozen symptoms indicate tubercular trouble, yet one or more important symptoms are absent. It requires, therefore, careful sifting of all the evidence, and close observation, as a safe guard against error.

Sarcoma, as a rule, especially in children, is of rapid growth and ordinarily accompanied by severe pain in the early stage. In my experience, in adults, it springs frequently from the ilium rather than from the femur, and these cases are incapable of being benefited by operative procedures. Sarcoma is much more common than carcinoma in this region. The central growths are ordinarily of the giant cell variety.

Suppuration, in my experience, is rare; in fact, I do not recall an instance in which it has occurred. The patient usually dies from exhaustion, or from systemic infection, or a blood vessel transference of the disease or some other organ, even before rupture of the skin and hemorrhagic protrusion of the contents take place. When suppuration does occur, I believe that it usually arises from other inflammatory elements—probably traumatic.

# TRANSLATIONS.

## THERAPEUTICAL SUGGESTIONS FROM FOREIGN JOURNALS.*

### INFLUENZA, BRONCHITIS AND BRONCHO-PNEUMONIA.

In *Revista Clinica Terapeutica* (No. 12, 1893) the sulphate of codeine is recommended, in the treatment of the grippe, bronchitis and broncho-pneumonia, in the following formula:

℞ Salicylate of Cinconidine.
Hydrate of Terpene,....āā 18-30 (grs. ijss-v).
Sulphate of Codeine,....5-75 mgms. (1-13 to 1 1-16 grs. gms).

Sufficient for one capsule. Make twenty such capsule. One every 2-4 hours.

### ACETANILID AND DOVER'S POWDER IN GRIPPE.

Dr. E. Graetzer (*Wiener Medizinische Presse,* No. 6, 1894), in the treatment of the grippe recommends a combination of Dover's powder and acetanilid which he has employed, with the best results:

℞ Acetanilid..... 25 cgms. (grs. iv).
Dover's Powder..... 15 cgm. (grs. ijss).

One powder three times a day.

### PERMANGANATE OF POTASH IN ACUTE POISONING BY PHOSPHORUS.

Dr. Adolf Kelemen (*Pester Med. Chirurgische Presse*, No. 3, 1894) in support of the efficacy the permanganate of potash as an antidote in poisoning by phosphorus, reports the following case: A peasant woman of fifty-four years, dissolved the heads of four packages of matches in water and drank the solution, at eleven o'clock in the morning. The writer was called at half past two in the afternoon, when he found her in bed restless and continuously vomiting. Her gastric region was painful, her face pale, her pulse rapid and full. He had brought with him two quarts of a 1 per cent. solution of the permanganate which he had her drink by the glass full every three to four minutes. Within two hours she drank over a quart of the solution and vomited twice. He then left the patient, with instructions to drink the remainder. The next day she complained of violent pains in the stomach and had vomited three times. He ordered another quart of the solution to be drunk. For three days the gastric pains continued and coagulated blood was found in the vomit. As a beverage she received albumen water. From the fourth day the pains decreased in intensity, the vomiting did not reappear and her general condition so improved that she could be regarded as cured. The writer has observed several cases of poisoning by phosphorus, yet this is the only recovery that he has known. As all others ended fatally he can only ascribe the result to the permanganate.

### MASSAGE IN INTESTINAL INCARCERATION IN CHILDREN.

Dr. Maiss (*La Semaine Medicale*, No. 72, 1893), treated a child of nine months who after an attack of indigestion was seized with symptoms of obstruction. A sausage-like tumor was found in the region of the descending colon which extended into the left iliac fossa. In spite of large doses of opium the condition of the patient became worse and a laparotomy seemed indicated, but before operating he tried massage. With the pelvis elevated the right hand was placed over the iliac tumor, thus fixing it, while with the left hand the lumbar region was compressed. The tumor was then pushed upwards towards the diaphragm and immobilized and effleurage done from left to right. After a few such movements, with deep pressure, the tumor together with all the symptoms of occlusion, disappeared. Dr. Barder, in the same journal, records two other cases. The first was a child fifteen days of age, where opium and intestinal irrigation were without effect. By bimanual examination he was able to make out a cylindrical body, seven to eight cms. in length, which lay obliquely in the left hypochondrium; invagination of the colon in the ileum. A few frictions with the right hand, from left to right, produced a marked relief. A second and more energetic massage caused the tumor and the symptoms to disappear. The third case was that of a girl of eighteen months, who had suffered for several days from diarrhœa and who was seized with symptoms of incarceration after an attack of coughing. In

*In charge of the translator, F. H. Pritchard, A. M., M. D.

the left iliac fossa a sausage-shaped swelling could be outlined through the abdominal wall. A few seances of massage, with the little finger of the left hand in the rectum and with the right hand pressing on the tumor, gradually caused it to disappear.

### QUININE IN INFLUENZA.

Dr. Graeser (*Wiener Medizinische Presse*, No. 3, 1894), has employed quinine in the epidemic of 1889-90, in the Poliklinik at Bonn, and claims that the patients thus treated suffered less from after-effects of the disease. Only three reappeared for treatment the second time, while of those who received other remedies over half came the second or third time. The depression and feeling of tiredness were of much shorter duration than those under other treatments. It was also employed prophylactically. In Bonn the soldiers of a regiment received seven and a half grains of the sulphate in half an ounce of whiskey every day for twenty-two days. Though some fell sick, fewer were attacked than in other regiments or in another in the same garrison. From his experiments he regards quinine as a specific in influenza.

### PETROLEUM IN CANCER AND VAGINITIS.

Dr. Desprès (*Centralblatt fur Gynækologie*, No. 48, 1893), recommends ordinary refined coal oil in the treatment of cancer and vaginitis. In ordinary inoperable carcinoma of the uterus he injects it into the tumor and applies it on tampons in the vagina or uses it in irrigations. Injected into abscesses it causes healing to take place, removes the disagreeable odor of disintegrating carcinomata, especially of the uterus, causes the gangrenous surfaces to be cast off and the ulcerations to become dry. In vaginitis he has also employed it with success as injections and claims that after three daily injections of four to five ounces of the oil, a cure will be obtained in six days. Petroleum has the advantage of easily diffusing itself, deodorizing and disinfecting and yet not irritating the mucous membranes. If applied to an already inflamed mucous membrane it has caused vesicles to form. The patients did not complain of the odor nor was their general health affected.

### QUININE IN WHOOPING COUGH.

Dr. P. Baron (*Wiener Medizinische Presse*, No. 3, 1894), has tried quinine in fifty cases of whooping cough and is well satisfied with the results. In a few of the children a favorable result was observed at once, especially on the second to third day. But in the majority the results were varying for several days, as they were inclined to vomit and unequal quantities of the drug were absorbed. The stage when the drug is administered has quite an influence. From the fifth to the sixth day a decided improvement as to the number and severity of the attacks may be relied upon. When improvement has once set in it still will continue even if the remedy be given in smaller doses. On an average three weeks were required to effect a cure; in some cases the action is actually abortive. No relapses. It is especially valuable in cases accompanied by acute pulmonary affections. The single dose is one-fifth of a grain per month and one and a half grain per year, of the child's age, three times a day. It is best given in the morning at six, in the afternoon at two, and in the evening at ten o'clock. More than three doses per diem, or six grains, for children over four years is not necessary. If improvement has set in distinctly then do not give more than two daily doses, then decrease it gradually and after nearly complete recovery, let them take a dose in the evening. If the appetite is deficient prescribe hydrochloric acid.

### NEURALGIC DYSMENORRHŒA.

In the *Rivista Clinica e Terapeutica*, No. 12, 1893, the following formula is spoken highly of in neuralgic dysmenorrhœa:

℞ Extract opium.....10 cgms (grs jss)
Extract belladonna.....10 cgms (grs. jss)
Sulphate of quinine.....1½ gms (grs xxijss)
Sufficient for twenty-five pills. One every three hours.

### SACCHARATED SOLUTION OF IRON AND MANGANESE.

In the *Union Médicale*, No. 49, 1893, the following formula is presented:

℞ Saccharated oxide of iron.....200 gms (℥vjss)
Distilled water.....700 gms (℥xxjjss)
Crystallized chloride of manganese 3.7 gms (grs. xlv).

Dissolve the iron in the other two constituents, then add:

Distilled water..... .....15 gms (3iv)
Sol. citrate of ammonia..... 25 gms (3vj)
Alcohol.. .. .....50 gms (3jss)
Tint. orange peel..... 3 gms (gtts. xlv)
Tinct. vanillia..... 1 gm (gtts xv)
Acetic ether.....gtts. v.

---

ICHTHYOL IN ACUTE OTITIS MEDIA.

Dr. Solt (*Gazetta Degli Ospitali*, No. 150, 1893), on account of the good results which have been obtained in metritis with ichthyol, has tried it in acute otitis media. He advises the following formula:

℞ Ichthyol.....1 gm (grs. xv)
Glycerine..... .....
Distilled water, āā.....7½ gms (3ij)

Drop a few drops of this mixture into the meatus three times a day.

He claims that it exercises a very favorple result in acute otitis media. The pains cease rapidly and the inflammatory symptoms gradually disappear.

---

CASTOR OIL ADMINISTERED AGREEABLY.

In the *Gazette Degli Ospitali*, No. 150, 1893, it is asserted that if one shake a mixture of castor oil in warm milk, in a bottle, an agreeable emulsion is obtained. The disagreeable odor and taste are thereby masked.

---

TREATMENT OF HEADACHE IN CHLOROTIC PATIENTS.

Dr. Albert Robin (*Gazette des Hopitaux*, No. 10, 1894), advises the following formulæ in the treatment of the headache of chlorotic subjects:

℞ Powdered paullinia.....20 cgms. (grs. iij).
Extract of cannabis indica..... 1 cgm. (gr. jss).

Sufficient for one pill. Three pills a day.

℞ Antipyrine .....50 cgms. (grs. vijss).
Mur. cocaine.....1 " (grs. jss).
Caffeine.....1 " (grs. jss).
Bromide ammonia.....50 " (grs. vijss)
Iodide ammonia.....50 " (grs. vijss).

Sufficient for one powder. One per diem.

℞ Phenacetine.....25-50 cgms. (grs. iv-vijss).
Exalgine.....10-15-25 " (grs. jss-ijss-iv).

Sufficient for one powder. Two per diem.

Ferrous preparations may be tried, but the results are variable. Menthol externally may be of service.

---

HYDRASTININE IN EPILEPSY.

Dr. Kisselew (*Le Mercredi Medical*, No. 51, 1893) on account of the anti-convulsive action which he has observed hydrastinine to exercise on animals, has tried it in epilepsy. It was administered internally in a watery solution, in a dose of one to two cgms. (1-6—1-4 gr.) and five doses, per diem. In all he gave it to four patients. In two the result was negative, while in the other two, after two or three weeks of treatment, there was a remarkable diminution, both in the intensity and frequency of the attacks. No inconvenience was observed from its use.

---

MANY people cannot understand why the small pox at present continues to crop up in new localities, and seems unconquerable. One of the reasons is to be found in the ignorance and turpitude of the tenement-house population, especially among the recently-arrived Italians. One of the special inspectors appointed by Dr. Doty to look out for suspicious cases, was directed by a policeman to a tenement in Mott street, on February 25th. The inspector found the doors to the room on the top floor locked and barred. Threats to arrest the inmates had no effect, and finally the doors were broken in. A search of the rooms revealed no sick person, but just as the doctor was leaving he heard some one sneeze. The sneeze seemed to come from a big trunk in the corner, and lifting the lid, he found an Italian boy beneath some bedding. The boy was covered with the eruption of small pox, and had been sick five days, and had no medical attendance. On the floor below, where also the doors had to to be broken in, there were two children hidden away. One had been attacked twenty days ago, and was now recovering; the other, a girl, four years old, was very ill of the disease. This tenement shelters twenty-five families, of Irish and Chinese, and, of course, a corps of officers was at once set to work searching all the tenements in the neighborhood and vaccinating the occupants. In a tenement in West thirty-sixth street, no less than five cases were found, and the officials were not resisted, it was found that though the two families affected many other persons had been exposed. It is plain that nothing but the constant vigilance and actual vaccinating work of Dr. Doty's men saved us from a wide diffusion of the disease.—(*Ind.*)

## EDITORIAL.

### TREATING PULMONARY TUBERCULOSIS WITH TUBERCULIN.

In a paper read before the Climatological Society, last May, by Dr. Karl von Ruck, Koch's tuberculin was shown to possess curative properties greater than has recently been attributed to it. Twenty-five cases that had been treated with it were reported. These were divided into three classes: *Class A*, included three patients, "who had one or both upper lobes involved, but without destructive changes, the general health of these patients being comparatively good." *Class B.* Patients "with more extensive disease or moderate destructive processes, but still in a fair physical condition." *Class C.* Cases "still further advanced in local disease, with considerable constitutional impairment, but still in a condition justifying some hope of improvement." In class *A*, five patients were treated and all recovered. In class *B*, seven cases were treated, of which six recovered and one was improved. There were thirteen belonging to class *C*, of which seven died and six were improved and still living.

Much of this success is attributed to the method of administering the tuberculin. The initial dose used by von Ruck was 1-20 milligram and the quantity was gradually increased by tenths of a milligram until one milligram was given. Then the increase was by fifths up to two milligrams; then by halves up to ten; by doses of two and a half milligrams up to twenty; and thereafter by doses of five milligrams at a time. Periods were observed when for weeks together no local or general reaction was observed, while the improvement of the patient progressed favorably; and whenever a point had been reached where this improvement was radical and active symptoms had entirely subsided, the administration ceased, allowing an intermission of from two weeks to a month. If no relapse had occurred in this time, if every symptom and indication was favorable, the patient was kept under observation. If the result was not satisfactory a repetition of the treatment was necessary.

In the second course the initial dose was

1-10 milligram, but increased after each dose so long as no local reaction occurred.

These results are encouraging, but the fact should be borne constantly in mind that it is in the early stages of the disease that the greatest benefit was received. The practical importance of this is the necessity for early diagnosis, a fact well known to all physicians, but often neglected until the disease has advanced so far that the diagnosis is evident from the advanced lesions produced. Again the fact should not be overlooked that von Ruck had the benefit of excellent climate and the perfect control of his patients which he himself admits were valuable adjuncts.

However, his results are encouraging and the evidence quite conclusive that much benefit was obtained by the use of tuberculin.

## STERILIZING MILK AT A TEMPERATURE OF 75° C.

Freeman (*Med. Rec.*, June 10, 1893), has contributed an article of much interest on the sterilization of milk at a temperature of 75° C. (167° F.). This is known as *pasteurization* of milk.

The method formerly employed to sterilize milk was to heat it to a temperature of 100° C. (212° F.)—or to the boiling point. This process was found to produce many changes in the milk which renders it less digestible. The casein is rendered less coagulable by rennet, and is acted on slowly and imperfectly by pepsin and pancreatin. Milk sugar is destroyed.

Pasteurization, however, furnishes a food which is practically sterile during the ensuing twenty-four to forty-eight hours; a food on which infants seem to thrive, and which has undergone practically no modification from heat. Milk prepared in this way is not intended for keeping several days but should be prepared daily.

The author had repeated many of the experiments to determine the thermal death point of certain pathogenic bacteria which may find their way into milk. His conclusions are as follows:

1. "Pasteurization of milk at about 75° C. affords a safe guard against deleterious effects of any bacteria which it may contain, without interfering with its nutritive qualities.

2. "Pasteurization at about 75° C. (167°F.) destroys efficiently the germs of cholera, typhoid fever, diphtheria, and tuberculosis, as well as the streptococcus pyogenes, the staphylococcus pyogenes aureus, and the bacillus coli communis."

3. "Pasteurization at about 75° C. does not modify the size of the curd formed when milk is subjected to the action of the gastric juice."

4. "Milk after pasteurization is best cooled in a water bath."

5. "Pasteurization at about 75° C., may be used after peptonizing to stop the action of the ferment."

---

THE crusade of the State Boards of Health against quacks, brings to light some queer characters, and presents a melancholy spectacle of dupes who pour money into the pockets of these unprincipled harpies. At one of the meetings of the State Medical Society of Missouri, an account was given of an old impostor in the northern part of the State who claimed to have wrought miracles of healing "with only three remedies," all from a certain root. *Highbobalorum* was obtained by peeling the root upward, and was a certain emetic. *Lobobalorum* was obtained by peeling the same root *downward*, and was a sure cathartic; and *Hilobustem*, by peeling the root around, was a rank poison and would carry everything before it was only to be used when the others had failed.—*N. Y. Med.*

## PROTOZOA AND CARCINOMA.

There is probably no subject in pathology over which there is more earnest controversy than the etiology of cancer. That cancer is due to the presence of a protozoan, has been positively asserted by certain investigators, while others maintain that it is not of parasitic origin.

Adler (*Amer. Jour. Med. Sci.* Jan. 1894.) gives the results of his study of cancer, in which the adherents of the protozoan theory can not find pleasure. He has studied the subject for over three years, has used many methods of investigation, and has examined over 60 cancers from different parts of the body.

After a careful discussion of the subject he draws the following conclusions:

"The existence of parastic protozoa in cancer is probable, though the greater part of what has hitherto been described as parasitic is certainly not so. No constant or in any way specific organism has as yet been demonstrated beyond possibilities of doubt. At present no facts, histological or otherwise, compel the asumption of a parasitic origin of carcinoma, while there are very strong and valid arguments against such assumption."

# ABSTRACTS.

## TWO CASES OF HERNIA OF THE FALLOPIAN TUBE.

Dr. Morton reports a case of a woman, forty-six years of age, who sought advice at the out-patient department of the Royal Surrey County Hospital, on account of a swelling in the right groin. She had had a swelling there constantly for two years, and it had suddenly become larger five days before she attended the hospital. There had been no action of the bowel for five days. The swelling was tender to the touch and gave impression of an inflamed gland softening in the centre.

A simple enema was administered, and produced a considerable evacuation. Four days later an incision was made over the swelling through tissues which were of almost cartilaginous density. This exposed a rounded, grey, translucent mass, which looked almost like the colon, but was in reality the thickened sac. On opening the sac, a small quantity of coffee-colored fluid escaped. The sac contained some omentum and an irregular, varicose-looking mass, attached to one end of which were some congested papillary projections. These latter proved to be the Fallopian tube and its fimbriated extremity. The tube and omentum were returned and the sac was ligatured and cut away. The wound healed by first intention.

*Case 2.*—A woman was admitted to the Royal Surrey County Hospital suffering from a strangulated right femoral hernia, which had been down for five weeks. The symptoms of strangulation were of a fortnight's duration. A simple enema produced a copious evacuation, and this was followed by a copious natural evacuation some hours later. Herniotomy was performed and the sac was found to contain gangrenous omentum and gangrenous ruptured bowel. The peritoneal cavity contained a large amount of fæcal matter apparently mixed with pus.

The gangrenous omentum was removed, and an artificial anus made, but the patient died from shock twelve hours later.

At the post-mortem examination the bowel was found to be ruptured about eighteen inches above the ileo-cæcal valve. The omentum, small intestine, and cæcum were all much matted together, and glued to the surface of the mass so formed was the end of the right Fallopian tube, which was gangrenous to the extent of about half an inch, having evidently been caught in the constricting band. The vermiform appendix was apparently healthy, although the finding of an orange pip in the peritoneal cavity had given rise to a suspicion that the appendix might also be involved. —*The Lancet*, 1894.

# SOCIETY REPORTS.

## SECTION ON ORTHOPEDIC SURGERY OF THE COLLEGE OF PHYSICIANS OF PHILADEDPHIA.

*February* 17, 1894.

[Stenographically Reported by C. C. Mapes, M. D.]

DR. DEFOREST Williard opened the meeting by reading a paper upon "Sarcomatous or other tumors, which may in their early stages be confounded with hip disease." (See page 424)

### DISCUSSION.

DR. G. G. DAVIS: I do not remember having seen a case of sarcoma of the hip, but I recall two cases of tubercular disease in one of which an enlargement occurred above the trochanter and was supposed to be sarcomatous. It was operated upon and proved to be a collection of pus which had originated within the pelvis and come out of the greater sacro-sciatic notch. The swelling was the size of a small egg and being in that position and covered with muscle, it was difficult to be positive that fluctuation was present. I have seen, also, another case in which pus came from the same opening. The collection of pus arose from carious bone and worked its way downward and outward through the notch, and gave rise to the suspicion of tumor. A collection of pus so close to the hip joint might very readily give rise to a diagnosis of hip joint disease.

DR. T. S. K. MORTON; I have nothing to add to the presence of growths about the hip joint, but in thinking this matter over I recall a case of carcinoma of one mammæ, in a woman about forty years of age, which I saw several years ago. Some eight to ten months afterward she tripped when walking, and had a very slight fall to the floor which resulted in fracture of the neck of the thigh bone, and she died from shock. At the post-mortem was found metastasis of soft carcinoma throughout the body. The point of interest was the great destruction of the neck of the femur; it was almost replaced by soft carcinoma which left a thin shell of bone, so thin, that slight traumatism was sufficient to break it.

DR. BENJAMIN LEE: I have nothing to add to the history of such cases; judging from my own experience I should presume them to be extremely rare in comparison with tubercular disease of the hip joint. In regard to diagnosis I am of the some opinion as Dr. Willard. I should not expect these affections to have the same history as true hip joint disease; that is, to say, commencing with lengthening and eversion and going on to shortening and inversion. I presume that before such change could take place, the tumor would declare itself by its own characteristics. Another point of difference would be the absence of the starting pains, so characteristic of hip disease. One remark made by the author of the paper impressed me very much; and that was that in making his examination of these cases he had taken the pains to strip the patient so that the two sides could be compared, on this point I think we cannot insist on too strongly. I believe that the reason that the family physician often makes a mistake, and has to call upon an orthopedic surgeon for counsel is simply because he has neglected to make an examination, as Dr. Willard suggests, with the naked body before him. This should always be done, especially in suspected lateral curvature or hip disease; I consider it of the greatest importance.

DR. DEFOREST WILLARD: I have been called to the country twice this week in consultation, and in each case the physician could have made the diagnosis as well as I, if he had simply stripped his patient.

I remember a peculiar case on which Dr. Agnew operated for sarcoma of the breast. In twelve or fifteen months there was a return of the disease in numerous regions of the body. Both humerii were broken by very slight movement; one finger was snapped by being caught in the sheet of the bed and the other while being laid across her breast. Absolute union took place without any difficulty. The disease was progressive and she died a few months afterward. At the post-mortem was found a good callus, and no sarcomatous disease at the line of the fracture. It is interesting that in spite of the fragility of the bones, good union had taken place.

DR. F. SAVARY PEARCE: I recall no cases in the Orthopedic Hospital during my residency, of tumor of the hip, but I remember one of the upper middle third of the femur; it developed rapidly and had a fatal termination. The tumor was diagnosed sarcoma and was probably secondary to a malignant breast growth, removed some months previous. The woman was past middle life.

DR. G. G. Davis: I would like to ask Dr. Willard if he regards the condition as malignant disease of the humerii, or simply one of atrophy caused by the general dyscrasia. Cases of fracture occurring in malignant—particularly sarcomatous—diseases are not uncommon, but I would like to ask if this particular case was locally sarcomatous.

DR. DEFOREST WILLARD: I do not think there was sarcoma at the particular point which gave way. I believe the bones were fragile from the general condition, although there were probably twenty sarcomatous foci in other regions of the body.

There is no difficulty in diagnosing these cases in the later stages; it is in their beginning that a differential diagnosis is difficult to establish. I never saw starting pains in this condition. The pain is continuous and very severe with atrocious exacerbations, Starting pains make a very good diagnostic point.

DR. F. SAVARY PEARCE: A differential diagnosis must be made between malignant and simply ulcerated growths, and this is sometimes difficult. I heard of a case operated upon by Dr. Agnew who was misled by a large fatty tumor about the hip. The growth had ulcerated on the surface and a section was made for microscopical examination. It was reported malignant and the limb was amputated with a fatal result. Ulceration had occured over the growth which was a simple lipoma as stated. In this case the microscopist was at fault, not the operator.

"SARCOMA OF THE THIGH."

Presented by Dr. J. T. Rugh by invitation.

The case is one belonging to the Orthopedic Department of Jefferson Medical College Hospital, under the care of Prof. H. Augustus Wilson, and is extremely rare and interesting.

While there is no contra-indication to the development of sarcoma in hip joint disease, yet such a condition has seldom, if, indeed, ever been reported.

The history is as follows: W. W., aet. 19 years, born in Austria, and living in this country for the past two years. Family history good, personal history good until 15 years of age, when he fell striking heavily upon his right hip. The parts were quite sore for a few days but no special attention was given to the injury. In a few weeks pain and soreness developed and difficulty in walking was soon experienced.

These symptoms continued for several months, with occasional intermissions until the tenderness became extreme and enlargement of the part was observed; which gradually increased until one year from the receipt of the fall, an abscess ruptured on the posterior surface of the thigh and discharged very freely. Relief followed but the sinus remained patulous and in the next two years, or until January 31st, 1893, four new ones were formed. At this time he first came to the clinic and was admitted to the ward of the Hospital. Another abscess formed and an operation was deemed necessary. The bony involvement was evidently very great. On February 2nd, 1893, Prof. Wilson opened the part freely on the external surface just over the large trochanter and removed considerable dead bone. He also evacuated several pockets of pus. The acetabulum was extensively involved but was not disturbed. Drainage was obtained by rubber tubes, the wounded closed, and the usual dressings applied. Tubes removed in three days and parts dressed twice a day while in the ward. He was discharged on April 6th., 1893, very much improved in weight and strength. He has been dressed two or three times a week ever since.

In the latter part of December, 1893, a slight swelling appeared about 1½ inches below Pouparts ligament, extending downward and inward across the large vessels. This gradually increased and by the end of the first week in January, 1894, the circulation become hindered because of the situation and enlargement of the tumor. A week later flucuation could be detected at several points but it lacked the elastic and expansive feel of the true abscess, and was more like a transmuscular wave; but on account of the pre-existing ostitis, the rapidity of development and fluctuation, an abscess was diagnosticated by all who examined it. There were also enlarged veins; œdema (slight over the tumor but marked below it); no elevation of the temperature, no pain, no soreness, and no heat or redness.

On January 27th., 1894, Dr. Mann and I opened it in two places but found no pus. The finger introduced into the wound detected very soft, friable, and easily detached tissue. Hemorrhage was very profuse. Some separated pieces were examined and thought to be sarcomatous, both from appearance and feel. Closure of the wound stopped the hemorrhage and dressings were applied.

Sections of the tumor were made and examined by Prof. Coplin and Dr. Kyle but neither would say positively that it was sarcoma, yet both agreed that it had more the characteristics of such than of inflammatory tissue which it resembled.

The clinical history is plainly that of sarcoma for the list of local and constitutional symptoms entailed in the production of so extensive an inflammatory exudate are all absent. On Feb. 13th, when I removed the dressings, a large fungating mass existed at one of the incisions from which quite a

stream of blood flowed. The mass was about 1½ inches in diameter and was raised about ½ inch above the skin. The origin is very doubtful as there are many structures from which it might arise, but the probability is that it is of bony origin though it may be from the connective tissue of some old sinus, and caused by some irritative impression of the tubercular ostitis.

Removal of the growth would be impossible because of its size and situation. Amputation is also negatived by the widespread tubercular infiltration which exists. Comfort only can be offered though not insured.

(The patient was then brought in and examined by all present. Sections of the tumor were also shown with the microscope.)

DISCUSSION.

DR. J. K. YOUNG: This case should not be allowed to pass without some discussion, yet there is very little to be said. The opinion given by the pathologists is one that we often hear. My experience with pathologists has been very unsatisfactory, and I prefer to rely upon the clinical history and appearance. My opinion is that very little can be told by pathologists as to the character of a specimen until the death of the patient or the entire tumor is removed. This was particularly noticeable in a recent case in which the pathologists gave a report that it was malignant, but which was reversed upon more thorough examination. There are only two symptoms in the present case which point to its being benign. The growth appears to have occurred in the cicatrix of one of the sinuses, in the interior portion of a groin. It will probably be found that the femur had been the starting point. Fungoid tumors about the sinus are not uncommon and they have the characteristic appearance spoken of by Paget. The position of this sinus and the character of the growth would indicate the femur as the part involved. If in this case the tumor be benign, the bleeding and the œdema might be due to pressure upon the femoral vein. The great size would indicate a mass of granulated tissue in the capsule.

DR. G. G. DAVIS: This condition interests me because if it is sarcomatons it shows the co-existence of two diseases in the same neighborhood, and both of them marked ones. The sinuses are not all closed; there are four open ones, all discharging, and there must be active disease going on somewhere. The presence of active bone disease and active malignant disease in the same vicinity, both pursuing a marked course, is, I think, unlikely. Should it be the two diseases, it is most remarkable. I should not be willing to make a diagnosis without some hesitancy, and yet I would not be surprised at a pathologist making a diagnosis of malignant disease from the granulations surrounding the opening. I think there is at least some room for doubt as to the affection being malignant.

Dr. Mitchell has just made a suggestion as to the original disease having been malignant instead of tuberculous. I do not think this can be the case as the tubercular disease has existed for three years and pursued a steady course of clinical bone disease, and we know that sarcoma has no tendency to suppuration, and therefore I do not think that the primary disease was sarcomatous.

DR. DEFOREST WILLARD: The possibility of the disease having been sarcomatous from the first also occurred to me, but the clinical history is so characteristic of bone disease that the diagnosis seems very clear. I should rate it a tubercular ostitis. But its present condition I should not hesitate, however, to call a sarcomatous growth. It is an unusual case, I have never seen one like it. It is probably a sarcomatous disease which has become engrafted upon the cicatrix. There is nothing incompatible in the co-existence of the two diseases; it is altogether possible. In this case I do not think we can take any exception to the diagnosis made. The course will probably be rapid from this time.

DR. T. J. RUGH: There is one point to which I should like to call the attention of the section and that is in regard to the microscopical examination. The part for section was taken from the centre of the tumor itself. The tumor had not been opened until it had been opened by the knife. The point upon which the pathologists were in doubt was the condition of the blood vessels, which are thoroughly characteristic in inflammatory tumors, that is, the walls are thickened and enlarged, while in sarcomatous growths the blood vessels have no walls. In this specimen they found, in some parts, thickened walls; in other parts, none. That is my reason for the statement that they would not affirm or deny in favor of sarcoma.

DR. J. K. MITCHELL: It seems to me that the question of tuberculosis might readily be disposed of by the microscope or by cultivation.

DR. J. T. RUGH: I did not tell the pathologists from what part of the body the specimen was taken, nor anything of the clinical history, and their reports were based entirely upon the microscopical examination.

DR. SAVARY PEARCE: The talk seems to have drifted into the difference between *macroscopic* tubercular and sarcomatous conditions. *Microscopically* ulceration and sarcoma are allied. In October last I removed a breast from a case of my father's which had all

the appearance of malignant disease and was fungoid in character. The patient was a woman fifty-two years of age. There was no enlargement of the lymphatic glands. The pathologist who examined the specimen thought it sarcomatous; my father supposed it to be carcinomatous. At a meeting of the Pathological Society, a section was shown to Prof. Guiteras, who decided it to be intercanalicular-fibroma. The wound healed by first intention. The woman is now well. I speak of this because the difference in opinion of pathologists in diagnosing tumors is explained by the position of the different sections.

The round celled infiltration of ulceration can easily be mistaken for small round cell sarcoma, and with excuse. Sections from *many* parts of any growth should be studied before a safe opinion can be ventured as to malignancy or non-malignancy.

DR. DEFOREST WILLARD: Much as I respect the valuable services of the pathologist, I am still inclined to rely more upon the results of clinical experience,

DR. BENJAMIN LEE: The case impresses me very clearly as one of malignant disease. The peculiarities of the tumor, the nodes alternating with small areas of fluctuation; the size of the fungus excresence seem to me very characteristic, and not what we should find in a tubercular abscess. I noticed no sinus at the point of incision and excrescence. The sinuses are old ones in connection with the tubercular disease of the joint. The excrescence came from a new growth, with a history of only a few weeks. I cannot conceive it possible to have this fungoid condition as a result of tubercular disease.

## PHILADELPHIA COUNTY MEDICAL SOCIETY.

*Meeting February 14, 1894.*

Drs. Keen and Mitchell presented a paper entitled

### REMOVAL OF THE GASSERIAN GANGLION AS THE LAST OF FOURTEEN OPERATIONS IN THIRTEEN YEARS FOR TIC DOULOUREAUX.

#### DISCUSSION

DR. JAMES HENDRIE LLOYD; I had the opportunity of witnessing this operation by Dr. Keen, which has been followed by such brilliant results. I wish simply to discuss briefly the pathological aspect of this case, and to refer to a case which I have had under observation within the last year, and in which the termination has been satisfactory although no operative treatment was employed. With reference to pathology, it has been customary to attribute this affection to a peripheral origin and to fight it back, step by step, until, as it were, we reach it in its central location. I think that that should teach us that probably the disease is not really of peripheral origin in all cases, but that in some of these cases it is essentially a disease of the ganglion itself, and that probably the reason that so many of these operations fail is because at first the operation is confined to one or two isolated nerve trunks. The sensory nervous system originates in the ganglion. It is not of medullary origin in any sense. Embryologists and histologists know that the central nervous system is divided into two zones or areas, the so-called zones of His. The medullary zone including the motor system springs entirely from the cells of the anterior horns, and the sensory zone springs entirely from the ganglia of the posterior nerve roots. These ganglia of the posterior nerve roots, especially in the embryo, are of great relative size and importance and of considerable complexity of structure. As late as yesterday I had the opportunity of studying sections of the cord of the embryo pig. In these I was struck with the great size and evident importance of the ganglia of the posterior nerve roots from which the whole sensory system springs. They are almost one-quarter as large as the cord itself. The importance which I attach to this, especially in cases of this kind, is that we can readily see the analogy that may exist in diseases of this sensory zone and diseases that exist in the motor zone. It is well known clinically that some of our more important, progressive, and chronic diseases of the motor system originate in the multipolar cells of the anterior cornua. These diseases, such, for instance, as progressive muscular atrophy, are slow and insidious and attack the nerve cells one by one, and with this there is corresponding deterioration of the nerve fibre and ultimately of the muscular fibre. We can readily see that in diseases like trifacial neuralgia we may have an analogous condition in the centres which are in the large ganglia of which the Gasserian is a type. I think that in some of these cases we have a slow, insidious process going on in these ganglia which is reflected outward through the affected nerve trunks. These nerve trunks are attacked by the surgeon, but the insidious process keeps on and is reflected out over more and more of the nerve trunks that are left. This

is pre-eminently the history of these operations on the fifth nerve. This fact suggests to my mind that in all probability this trouble, just as is progressive muscular atrophy, is a disease of the ganglionic nerve cells.

The fact that a neuritis is found by the microscope in the excised nerve trunk does not in any sense invalidate this theory. The neuritis may easily be a continuation outward of a central process.
